13. Abstract
This report summarizes the results from an investigation of the behavior of cast-in-place (CIP) reinforced concrete (RC) box culverts. Load rating of CIP-RC box culverts has been a challenge for Departments of Transportation (DOTs) across the nation, including in Louisiana. Excessive conservatism built into the American Association of State Highway and Transportation Officials (AASHTO) Bridge Design Specifications (BDS) has led to situations where load posting, structural strengthening, or full replacement of culverts may be needed unless refined analysis methods are used to obtain more accurate results. Use of refined methods is a time-consuming burden to bridge engineers. Field inspections have not led to obvious conclusions that this class of culverts is under distress because of overloading, which was confirmed by an earlier project (Project 16-3ST)

sponsored by the Louisiana Transportation Research Center (LTRC) [1]. This project was initiated to explore the potential for developing a live load distribution (LLDF) formula that produces more consistent results, removes unnecessary conservatism, and conforms to safety levels targeted by AASHTO-LRFD BDS.

To address this challenge, a parametric study was conducted considering the key parameters known to influence the structural behavior of CIP-RC box culverts. The parametric study included 273 CIP-RC box culverts, which were analyzed using refined analysis methods to obtain more accurate results representing actual culvert behavior. Simplified analyses used by engineers were also conducted using several empirical LLDF formulas. A detailed study of the effects of various parameters on the straining actions was performed. Based on this study, the key parameters that affect live load distribution were identified, and a live load distribution formula was developed. The main advantage of the proposed formula is that it considers the secondary distribution of straining actions in the top slab, which is greatly affected by the wheel load position. Comparisons between AASHTO-LRFD BDS LLDF and the proposed LLDF formula were conducted to study how both formulae conform to AASHTO-LRFD BDS safety level requirements, as measured by the reliability index.

The predictions of straining actions using the proposed LLDF formula were found to produce more consistent predictions than the AASHTO-LRFD BDS LLDF formula. The unnecessary conservatism in predicting positive moments was removed, while the inconsistency in predicting shear forces and negative moments was greatly reduced. Therefore, it is recommended that CIP-RC box culverts be designed and load rated using the developed formula.

Project Review Committee

Each research project will have an advisory committee appointed by the LTRC Director. The Project Review Committee is responsible for assisting the LTRC Administrator or Manager in the development of acceptable research problem statements, requests for proposals, review of research proposals, oversight of approved research projects, and implementation of findings.

LTRC appreciates the dedication of the following Project Review Committee Members in guiding this research study to fruition.

LTRC Administrator/Manager

Walid Alaywan, Ph.D., P.E.
Senior Structures Research Manager

Members

Abstract

This report summarizes the results from an investigation of the behavior of cast-in-place (CIP) reinforced concrete (RC) box culverts. Load rating of CIP-RC box culverts has been a challenge for Departments of Transportation (DOTs) across the nation, including in Louisiana. Excessive conservatism built into the American Association of State Highway and Transportation Officials (AASHTO) Bridge Design Specifications (BDS) has led to situations where load posting, structural strengthening, or full replacement of culverts may be needed unless refined analysis methods are used to obtain more accurate results. Use of refined methods is a time-consuming burden to bridge engineers. Field inspections have not led to obvious conclusions that this class of culverts is under distress because of overloading, which was confirmed by an earlier project (Project 16-3ST) sponsored by the Louisiana Transportation Research Center (LTRC) [1]. This project was initiated to explore the potential for developing a live load distribution (LLDF) formula that produces more consistent results, removes unnecessary conservatism, and conforms to safety levels targeted by AASHTO-LRFD BDS.

To address this challenge, a parametric study was conducted considering the key parameters known to influence the structural behavior of CIP-RC box culverts. The parametric study included 273 CIP-RC box culverts, which were analyzed using refined analysis methods to obtain more accurate results representing actual culvert behavior. Simplified analyses used by engineers were also conducted using several empirical LLDF formulas. A detailed study of the effects of various parameters on the straining actions was performed. Based on this study, the key parameters that affect live load distribution were identified, and a live load distribution formula was developed. The main advantage of the proposed formula is that it considers the secondary distribution of straining actions in the top slab, which is greatly affected by the wheel load position. Comparisons between AASHTO-LRFD BDS LLDF and the proposed LLDF formula were conducted to study how both formulae conform to AASHTO-LRFD BDS safety level requirements, as measured by the reliability index.

The predictions of straining actions using the proposed LLDF formula were found to produce more consistent predictions than the AASHTO-LRFD BDS LLDF formula. The unnecessary conservatism in predicting positive moments was removed, while the inconsistency in predicting shear forces and negative moments was greatly reduced. Therefore, it is recommended that CIP-RC box culverts be designed and load rated using the developed formula.

Acknowledgments

The authors gratefully acknowledge the financial support provided by the Louisiana Transportation Research Center (LTRC) (LTRC Project No. 20-1ST) and the Louisiana Department of Transportation and Development (DOTD)

The authors also acknowledge Ahmed Elshoura, graduate student in the Department of Civil and Environmental Engineering, for assistance in developing initial numerical models for analysis of culverts.

The authors would also like to thank Jenny Fu (DOTD), former Bridge Design Administrator, and Dana Fang (DOTD), Assistant Bridge Design Administrator, for initiating the idea behind this project, providing pertinent information throughout its execution, and for supporting the effort.

Finally, special thanks are due to Dr. Walid Alaywan (LTRC), Senior Structures Research Engineer, for his support of the research team and guidance throughout the project's execution.

Implementation Statement

This study demonstrates that the designing or load rating of cast-in-place (CIP) reinforced concrete (RC) box culverts using the American Association of State Highway and Transportation Officials (AASHTO) Bridge Design Specifications (BDS) live load distribution (LLDF) formula leads to inconsistencies in safety levels for some culverts and introduces unnecessary conservatism for others. The Louisiana Department of Transportation and Development (DOTD) stands to directly benefit from this project by reducing these inconsistencies and bringing culvert design into conformity with target safety levels acceptable by AASHTO-LRFD BDS as follows:

1. The proposed LLDF formula eliminates unnecessary conservatism in positive moment predictions, thus eliminating or reducing the number of culverts that will require load posting without the need to conduct refined analyses.
2. The proposed formula also eliminates unconservative shear force and negative moment predictions resulting from AASHTO-LRFD BDS LLDF formulae, which will enhance the safety of CIP-RC box culvert inventory.
3. As a last resort, culverts that are still not passing load rating requirements can be analyzed using refined analysis methods before resorting to load posting, structural strengthening, or other interventions.

Dissemination of the findings from this project can help with broader implementation of the proposed new LLDF formula. For implementation into the AASHTO LRFD Bridge Design Specifications, AASHTO Committee on Bridges and Structures (COBS) and its newly formed subcommittee on Soil Structures can help.

Introduction

This report provides detailed investigation of wheel load distribution through earth fill for the design and load rating of cast-in-place (CIP) reinforced concrete (RC) box culverts. CIP-RC box culverts pose a challenge to bridge engineers in Louisiana and nationwide, as their load rating often results in low rating factors, which requires intervention by load posting, strengthening, or even replacement. Field inspections reveal that these culverts perform well with no signs of distress, which raises a question about current load rating procedures.

In this section, a brief review of how wheel loads are distributed for the design and load rating of CIP-RC box culverts is presented.

Live Load Distribution for CIP-RC Box Culverts

According to the NBI (National Bridge Inventory), culverts make up almost 140,000 out of the total national bridge inventory of over 616,000 [2], which translates into approximately 23% of the inventory. In Louisiana, the bridge inventory includes approximately 2,600 culverts. CIP-RC box culverts constitute a sizeable portion of the overall culvert inventory. Culverts have to be load rated like other bridges to ensure their structural integrity. However, following current load rating procedures for these culverts often yields unacceptable load rating factors even though their performance is acceptable with no signs of distress, such as cracking or excessive deformations. Unacceptable rating factors can lead to load posting, which restricts the use of the transportation network. Alternatively, upgrading these culverts may avoid load posting; however, the associated work may be cost prohibitive. Buried cast-in-place reinforced concrete culverts are known as a robust structural system that can withstand highway traffic because they behave as a highly statically indeterminate system. There are two main differences between the design of culverts and other types of bridges. First, single axle loads, and sometimes single wheel loads, are the controlling live load conditions for the design of culverts, as opposed to the gross vehicle weight (GVW) that controls the design of typical bridge spans. Second, the depth of the soil fill above any culvert is determined based on the hydraulics and roadway geometric conditions at the bridge site, which is known to vary greatly, and accordingly has a great impact on the live load effects on the buried culvert. In 2010, National Cooperative Highway Research Program (NCHRP) Project 15-29 produced Report 647, “Recommended Design Specifications for Live Load Distribution to Buried Structures” [3]. Simplified design equations (SDEs) for the structural response of buried structures based on three-dimensional (3D) analysis of 830

buried culverts were developed. The report also provides guidelines for conducting 2D and 3D modeling analyses for culverts that are not covered by the SDEs. In this work, the effect of pavement on live load distribution was ignored, which can have a significant effect on reducing actual pressures that reach the box. While this may be a conservative assumption for design purposes, it penalizes existing culverts with pavement over their top soil fill.

Live load effects from highway trucks are often assumed to spread as a surface load over an area whose dimensions can be determined based on a linear function of depth. Acceptable designs have been produced based on this approximation method for estimating the distribution of vehicular live loads through earth fill AASHTO Standard Specifications or Load Factor Design (LFD) [4]. Figure 1 shows a schematic of how live load pressures spread from the surface where the pressure is spread from the tire contact area (typically 10 in. x 20 in.) to a larger area at a given depth H . Three cases are shown representing (a) the case of a single wheel load, (b) the case of two single wheel loads from adjacent trucks in a passing mode, and (c) the case of two axles of the case described in (b). Currently, AASHTO (American Association of State Highway and Transportation Officials) LRFD (Load and Resistance Factor Design) Bridge Design Specifications [5] equations for estimating the distribution of vehicular live loads through earth fill led to increases in live load pressures on buried structures in comparison with AASHTO Standard Specifications [4]. Consequently, NCHRP sponsored an ongoing research project (Project 15-54) with the objective of proposing modifications to the culvert load rating specifications in AASHTO Manual for Bridge Evaluation [6] and revising AASHTO-LRFD accordingly. This is further exacerbated by the higher dynamic allowance in AASHTO-LRFD.

Figure 1. Area of live load distribution – (a) Single wheel (b) Two single wheels in passing mode (c) Two axles of two single wheels in passing mode (ACPA, 2011)

Reinforcement detailing also has its implications on reinforced concrete box culvert rating. Multi-cell structural systems are highly statically indeterminate and are therefore capable of resisting larger pressures than similar ones with lesser degrees of indeterminacy. However, the degree of indeterminacy of multi-cell box culverts may be reduced if the reinforcement

detailing at the corners is not capable of transferring the internal forces produced in such systems. Many of the CIP box culverts in Louisiana were built with old details that may fall under this category. Figure 2 shows one of these details, which reveals that (a) exterior wall reinforcement is not adequately embedded in the top or bottom slabs of the box and (b) a single layer of reinforcement in these walls, and at the ends of the top and bottom slabs, make them incapable of resisting negative moments that would generate in a fully rigid corner joint. Engineers have typically considered these connections to behave like hinges rather than rigid connections. The exact behavior of these corner joints can be confirmed from load test results.

Figure 2. Old LA-DOTD standard detail for a three-cell CIP box culvert

Current live load distribution estimation formulas in AASHTO-LRFD [5] specified governing equations for estimating axle load distribution for different earth fill height. Equation [1] can be used to estimate wheel load distribution dimensions, as shown in Figure 1-a, for culverts with low earth fill height (less than 2 ft., or 0.6 m.). On the other hand, Equation [2] represents wheel load distribution dimensions for culverts with fill height larger than 2 ft., or 0.6 m.

For $H_f \leq 2 \text{ ft. (0.6 m.)}$

$$E_p(\text{in.}) = 96 + 1.44 * S \text{ (ft.)} \quad [1]$$

$$E_s(\text{in.}) = L_T(\text{in.}) + LLDF * H_f \text{ (in.)}$$

For $H_f > 2 \text{ ft. (0.6 m.)}$

$$E_p(\text{in.}) = 10 + LLDF * H_f \text{ (in.)} \quad [2]$$

$$E_s(\text{in.}) = 20 + LLDF * H_f \text{ (in.)}$$

Where, H_f = earth fill height, E_p = distribution width in the direction perpendicular to span, E_s = distribution width parallel to span, S = Span length, L_T = length of tire contacting area parallel to span, and $LLDF$ = live load distribution factor. For culverts with low fill height, the distribution width perpendicular to span length E_p is based on a research study done in 2005. In that research, one of the main objectives of the study was to evaluate live load distribution width that can be applied to 2D FE modeling to obtain the same peak bending moments as 3D FE modeling [7]. Culverts with different conditions were studied; one-cell and two-cells, cast-in-place reinforced concrete, and precast concrete, with different span lengths, different element thicknesses, and different supporting conditions. Each culvert case was either 0 ft. or 2 ft. (0.6 m.) fill height.

Current AASHTO live load distribution equations are conservative, specifically for low fill height culverts, and give conservative internal forces for critical cross sections. This conservatism affects the rating process since it distributes live load to a narrower area, which in turn increases pressure intensity and internal forces and conducts low rating factors.

Load distribution width for axle load constitutes two components:

1. Distribution through the asphalt pavement and the soil layers, which can be called “primary distribution”
2. Distribution due to the slab flexural rigidity, called “secondary distribution”, which accounts for slab continuity in longitudinal direction, i.e. plate behavior.

In this study, the main target was to develop live load distribution formulas of axle load applicable for 2D FE models, in order to obtain the same internal forces (positive and negative moments) that result from 3D FE analysis. The formulas were developed so that the secondary distribution due to slab continuity is taken into account. Consequently, the formulas depended on conducting 3D FE analysis and comparing results with 2D FE analysis. The goal was to investigate how wide the live load needs to be distributed over 2D FE model to result in approximately the same values as 3D FE models. Furthermore, a parametric study to investigate the parameters that are in correlation with the distribution area was performed.

Earlier Research on Culverts in Louisiana

The Louisiana Transportation Research Center has funded several studies on buried culverts in the past. However, the work was mainly focused on metal culverts [8-11]. The light weight and flexibility of metal pipes make them an appealing alternative to other types of culverts. However, their susceptibility to corrosion is a disadvantage. In 1977, researchers started studying the durability of buried metal pipe culverts to address their corrosion in the harsh environments where they are commonly employed. This initiated the motivation for inspecting six different types of existing culvert metal pipes and four other new types to evaluate the rate and causes of corrosion and durability. The authors observed that asbestos-bonded, asphalt-coated galvanized steel culverts performed better than other types of culverts considered in the study after six years of in-service monitoring.

Several reports were published in the 1990s on coated metal pipe culverts [12-14]. The main focus of these studies was to investigate the feasibility of cathodic protection, both externally and internally, to prevent corrosion in corrugated steel pipes, hence reducing the costs of maintaining or replacing these types of culverts. In this research, cathodic protection was applied to retrofitted metal pipe externally and internally and monitored for two years. The same protection process was applied on a new metal pipe culvert and monitored for one year. The monitoring results indicated that cathodic protection was effective for existing pipes externally, but not internally. However, cathodic protection was effective for both internal and external corrosion protection for new culverts. The information from monitoring was used to develop a computer expert system software to assist designers in assessing the economics of employing cathodic protection systems in metal culverts in Louisiana.

Research Needs

As seen in the brief review of published efforts on live load rating of CIP-RC box culverts, live load distribution for design and load rating purposes has been the focus of many studies. Despite the differences in available live load distribution models, there is a consensus on the fact that current AASHTO-LRFD BDS provisions pose a challenge to bridge engineers, as these provisions produce conservative assessments that sometimes lead to load rating factors that require intervention by load positioning, structural strengthening, or full replacement. This imposes an additional strain on the limited available resources.

The immediate research need for culvert load rating is to provide a modified procedure for both load rating CIP-RC box culverts in the DOTD's inventory that were built using old standard details as well as designing new culverts. The modified procedure will address the challenges resulting from current AASHTO-LRFD BDS provisions by removing unnecessary conservatism. The long-term need in Louisiana and nationwide is to fully understand the different factors that affect live load distribution, including fill height, pavement type, soil type, and a culvert's structural and geometric characteristics. Based on this understanding, new live load distribution formulas can be proposed.

This study builds on the findings from an earlier study (LTRC Project 16-3ST) in which field testing of eight culverts was conducted to assess the load rating of the selected culverts as a first step towards addressing long-term needs [1]. The project confirmed the structural integrity of the field-tested culverts despite the low ratings obtained using current load rating procedures.

This report presents the findings from a project whose purpose was to develop more rational live load distribution formula for the load rating and design of CIP-RC box culverts. A numerical modeling approach was adopted for the task. Three- and two-dimensional (3D and 2D) finite element (FE) models were used to model culverts with various configurations and design parameters to understand the behavior of CIP-RC box culverts. The FE results were then used to assess the quality of straining action predictions using AASHTO-LRFD BDS and to develop a new live load distribution formula. Finally, reliability assessment was conducted for culverts analyzed using the AASHTO-LRFD BDS and proposed live load distribution formulas.

Literature Review

The literature is rich with work on the behavior and design of buried structures. Some of these studies date to as early as several decades ago (e.g. [15; 16]). From early on, there was evidence that culverts were overdesigned. For example, Frederick and Tarhini [17] conducted field testing of prototypes, which revealed that observed strain levels were low.

The National Cooperative Highway Research Program sponsored several projects addressing culvert design. NCHRP Project 12-45, “Recommended Specifications for Large-Span Culverts”, involved monitoring the performance of full-scale metal and concrete culverts during backfilling and under vehicle loads [18]. The experimental results were complemented with finite element analyses whose results were used to create simplified design equations. NCHRP Project 15-29, “Recommended Design Specifications for Live Load Distribution to Buried Structures”, also produced simplified design equations for structural response based on 3D analysis of 830 buried culverts [3]. Finally, NCHRP Project 15-54, “Proposed Modifications to AASHTO Culvert Load Rating Specifications”, has been recently completed [19].

For culverts with low fill height, the equation for distribution width perpendicular to span length E_p is based on a research study completed in 2005. In this study, one of the main objectives was to evaluate live load distribution width that can be applied to 2D FE modeling to obtain the same peak bending moments as 3D FE modeling [7]. Culverts with different conditions were studied: one-cell and two-cells, cast-in-place reinforced concrete, and precast concrete, with different span lengths, different element thicknesses, different supporting conditions, and each culvert with 0 ft. or 2 ft. (0.6 m.) fill height. In that study, 3D finite element analysis was used to model the culverts described earlier. To obtain the load distribution width corresponding to maximum shear, maximum positive moment, and maximum negative moment, the wheel load was placed at a distance d (the effective top slab thickness), mid-span, and several intermediate locations, respectively. Distribution width corresponding to peak shear force was the smallest followed by positive bending moment and negative bending moment, which can be considered as a controlling distribution [7]. Based on this result, a conservative axle live load distribution equation was developed to be used for the design and rating of culverts with earth fill height less than 2 ft. (0.6 m.).

Abolmaali and Garg [20] tested six culverts up to failure to evaluate the shear capacity for box culverts. They were loaded by AASHTO HS-20 wheel loads at shear-critical locations. Tests showed that fine flexural cracks were initiated inside the top slab at an applied load

equal to approximately the factored load. Then, by increasing the applied load, more positive and negative flexural cracks were propagated until it reached 156% of the factored load, at which shear cracks started to be detected [20]. Culverts were observed for total failure at loads equal to twice the factored load, and flexure and bond slippage was the failure mode [20]. Consequently, it can be concluded that shear behavior is not the controlling mode of failure. Moreover, a 3D simulation study including finite element analysis for the previously described study has been performed to detect the crack propagation and failure pattern. The results were the same; increasing the load up to twice the factored load led to widening the flexural cracks, and shear cracks started to surface [21]. Those findings contradict what has been concluded in AASHTO-LRFD distribution equation.

Abdel-Karim et al. [15] discussed the distribution of wheel loading within the aforementioned stages (pavement layers, embankment soil, and top slab) by conducting live load tests on culverts with fill heights ranging from 2 ft. (0.6 m) to 12 ft. (3.65m), and load pressures were measured using pressure cells. The study concluded that load pressure is generally distributed over a square area, but increasing fill height uniform pressure intensity over a larger area with lower peak, except for 2 ft. (0.6 m) fill height. Furthermore, flexural rigidity of rigid pavement was shown to have considerable contribution in distribution loads within a wider area, with lower intensity specifically over low fill height culverts, owing to its higher flexural rigidity compared with soil rigidity. Moreover, the study proposed a method for calculating an additional width that represents the existence of rigid pavement by converting the pavement thickness into an equivalent fill height. The same behavior was also noticed for the top slab that helps for the additional dispersing of load, owing to the flexural rigidity of the top slab of the culvert.

Orton et al. [22] tested reinforced concrete culverts with fill depths ranging from 2.5 ft. (0.76 m.) to 13.5 ft. (4.1 m.) to determine live load effect on culvert behavior. By comparing measured and calculated strains and displacements, it was concluded that the AASHTO-LRFD specifications are overly conservative.

The accuracy of axle distribution equation stated in AASHTO-LRFD specifications was investigated by assessing the live load rating of three RC box culverts with different properties: span lengths, box dimensions, and earth fill heights. For each culvert, two different FE models were constructed. The first model is a 2D FE model using a structural-frame element for culvert component, and for wall and slab section; the second one is a 2D soil structural interaction. The models were calibrated by performing live load test and comparing test results with FE analyses. In the frame models, live loads were distributed based on AASHTO specifications, whereas they were dissipated according to the soil mesh in

the soil-structure interaction model. The research showed that both models are conservative, but more precise results were obtained from the 2D soil-structure interaction model. Moreover, increasing soil fill height resulted in improving the accuracy of both models [23]. Another study done by Wood et al. discussed the precision of live load distribution on RC box culverts. Comparison between three simplified FE models (structural-frame model, top-slab calibrated soil-structure model, and fully depth-calibrated soil-structure model) was conducted. In the first model, the soil was considered as a dead load only; it attenuated the wheel (concentrated) live load as recommended in the specifications [6], and it was found that it underrates culverts [24]. For the second model, axle line load is applied at the ground surface, and it is distributed to the walls, top slab, and the bottom slab of the culvert. More accurate load rating factors resulted using that model since it distributes stresses at the bottom slab and best captures the structural response. The fully depth-calibrated soil-structure model was found to obtain the most accurate and precise load factor since live loads are distributed differently according to the studied critical sections.

Acharya et al. [25] investigated the effect of the presence of rigid pavement and culvert span length on the live load distribution. It showed that the presence of rigid pavement enhanced the rating factor of culverts, owing to the additional live load distribution resulting from concrete pavement rigidity. An inverse correlation between load pressure intensity and span length was also found. In other words, increasing span length helped to distribute the live load within a wider area with less intensity, especially for culverts with low fill height.

Other parameters were studied in another study by Acharya et al. [26], in which RC box culverts with low fill height were tested with static and moving live load. The study aimed to understand the influence of vehicular axle load, its speed, and pavement type on top slab deflection of buried culverts. The tests were run under a static load at three different locations: concrete pavement, concrete shoulder with a thinner concrete pavement, and unsurfaced area, in addition to live load dynamic test. Tests showed that the deflection of top slab over the unsurfaced area due to the static load were 2-3 times higher than deflection under the concrete-paved road and shoulder as a result of the high stiffness of the concrete pavement. It was also observed that the dynamic load caused deflection with a higher magnitude than static loads due to impact effect.

Frederick and Tarhini [17] conducted a study to evaluate the design of precast reinforced concrete box culverts complying with ASTM Specifications C789 and C850 using AASHTO live load distribution provisions. The experimental program employed 1/6-size scale models and 1/24-size photo-elastic model of three culvert prototypes with different dimensions. By comparing the strains and deflections resulting from the model test and field test results of

the culvert prototypes, authors noticed that AASHTO live load distribution equation is conservative, and that the live load is dissipated over a wider area. It was concluded that culverts designed according to ASTM C850 were over-designed.

In general, current AASHTO-LRFD BDS live load distribution equation for low fill height culverts gives conservative internal forces at critical cross sections. This conservatism affects the rating process since it distributes live load to a narrower area, which in turn increases pressure intensity and internal forces and conducts low rating factors. In this study, the main target is to develop distribution equation E_p of axle load that can be used for 2D FE models to be able to obtain the same mid-span moment as 3D FE analysis. The proposed equation is based on conducting 3D FE analysis and comparing results with 2D FE analysis. A parametric study to quantify the correlation between 2D and 3D results for the distribution width E_p is also performed.

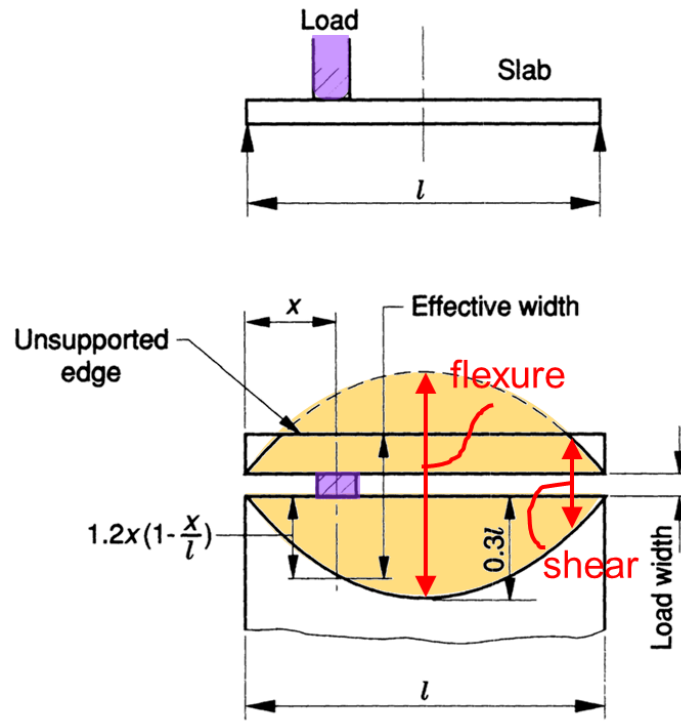

Secondary Distribution of Non-Uniform Loads on Slabs

Slabs are typically designed to resist uniformly distributed loads, which is easily handled by considering unit-width strips that are representative of the entire slab area. The complexity of the behavior of slabs increases substantially when subjected to non-uniform loads such as mast loads, partitions, and wheel loads. This topic has been investigated thoroughly by researchers since the 1930s [27]. Studies by Westergaard and others show that the portion of the slab that resists non-uniform loads extended beyond the projection of the load footprint on the slab. To some extent this concept has been implicitly adopted in AASHTO-LRFD BDS design provisions for bridge deck slabs and slab bridges. In AASHTO-LRFD BDS, the traditional design method identifies the strip width as a function of the span length. Other codes provide more explicit distribution width based on the position of the non-uniform load. For example, the Australian code has the following equation for determining the effective width (b_{ef}) of a slab that resists an applied non-uniform load:

$$b_{ef} = \text{load width} + 2.4 a \left[1 - \frac{a}{L_n} \right] \quad [3]$$

Where, a is the distance from the non-uniform load to the closest support and L_n is the span length of the slab. This and similar expressions show that for load positions critical for shear (i.e., close to the support), the distribution width is smaller for flexure critical load positions (i.e., close to midspan). This is illustrated in Figure 3. This topic will be revisited when the new LLDF is developed later in the report.

Figure 3. Effect of load position of width or slab resisting non-uniform loads

Objective

The primary objective of this project was to investigate live load distribution over buried cast-in-place (CIP) reinforced concrete (RC) box culverts in order to recommend the most appropriate live load distribution formulas (LLDF) for use in design and load rating.

The goals of the project were to:

1. Conduct a parametric investigation of buried RC-CIP box culverts covering key parameters known to affect distribution of wheel loads through the soil, both onto the culvert's top slab and structurally through the culvert.
2. Analyze results from the parametric study to help evaluate the best LLDF for the design and load rating of RC-CIP box culverts.
3. Study the reliability of RC-CIP box culverts using different LLDF to ensure conformity with AASHTO-LRFD BDS.
4. Provide DOTD with recommendations to assist in adoption in the *Bridge Design and Evaluation Manual (BDEM)*.

Scope

This study focused on cast-in-place (CIP) reinforced concrete (RC) box culverts buried under low earth fill height. In Louisiana, load rating this class of culverts is challenging because the live load distribution formulas (LLDF) adopted in AASHTO-LRFD BDS appear to be conservative. The load rating challenge is further exacerbated by the fact that standard details for CIP-RC box culverts provide no resistance to negative moments at the outside top corners of the culverts despite their good performance in the field. This good performance is evidenced by routine field inspections and live load tests conducted through LTRC Project 16-3ST [1].

Thus, the scope of investigation is limited to CIP-RC box culverts with low earth fill heights (≤ 2 ft.) considering AASHTO-LRFD BDS design axle loads, namely design truck and design tandem loads. 1-, 2-, and 3-barrel culverts with different sizes were considered in the investigation.

Methodology

To study both the live load distribution of design wheel loads through the soil onto the culvert and with the cast-in-place (CIP) reinforced concrete (RC) box culverts, detailed numerical models were used. The finite element (FE) method was chosen for this task, as it provides flexibility regarding the level of detail that can be considered in the model (e.g. modeling subgrade as springs, compression-only springs, or a continuum with contact elements).

Modeling of Buried Box Culverts

The numerical models used in this study were developed to provide a more exact assessment of live load distribution of wheel loads through the earth fill on top of the culvert and within the culvert itself. This distribution can only be captured using two-dimensional (2D) models after introducing empirical approximations that make the process inherently conservative. Conversely, three-dimensional (3D) models capture the distribution of wheel loads more accurately based on the mechanics of how the slab interacts with surrounding structural elements, rather than based on empirical assumptions. Since the use of 3D models is expensive and requires advanced knowledge of the finite element method, engineers typically use 2D models in the analysis of CIP-RC for design and load rating purposes. Therefore, all culverts investigated in this study were modeled using both models (2D and 3D), which are described next.

Three-dimensional (3D) Modeling of CIP-RC Culverts

Three-dimensional (3D) structural models represent the modeled structure in space without introducing simplifications that result from the elimination of the third dimension. For example, wheel loads attenuate through the soil and only affect a region of the culvert's top slab in the vicinity of the wheel load locations. The effect of the wheel load far from where it is applied becomes negligible as the distance from the wheel load increases. This effect is accounted for based on the structural response of the culverts as opposed to empirical simplifications of the transverse length of the culvert affected by the wheel load. Figure 4-a shows a 3D model of a 3-barrel culvert case with an axle load acting on the middle of the first barrel span. The culvert's top slab would deflect under the shown axle load, as can be seen in Figure 4-b. It is clear that the region affected by the axle load is limited near the application of the axle load. This region is clearer in Figure 4-c where the contour plot of the

vertical displacement highlights the region affected by the applied axle load. As stated earlier, the extent of this region transversely (i.e., perpendicular to traffic) is empirically estimated in 2D models.

Figure 4. Three-dimensional (3D) model of a 3-barrel culvert with one axle load

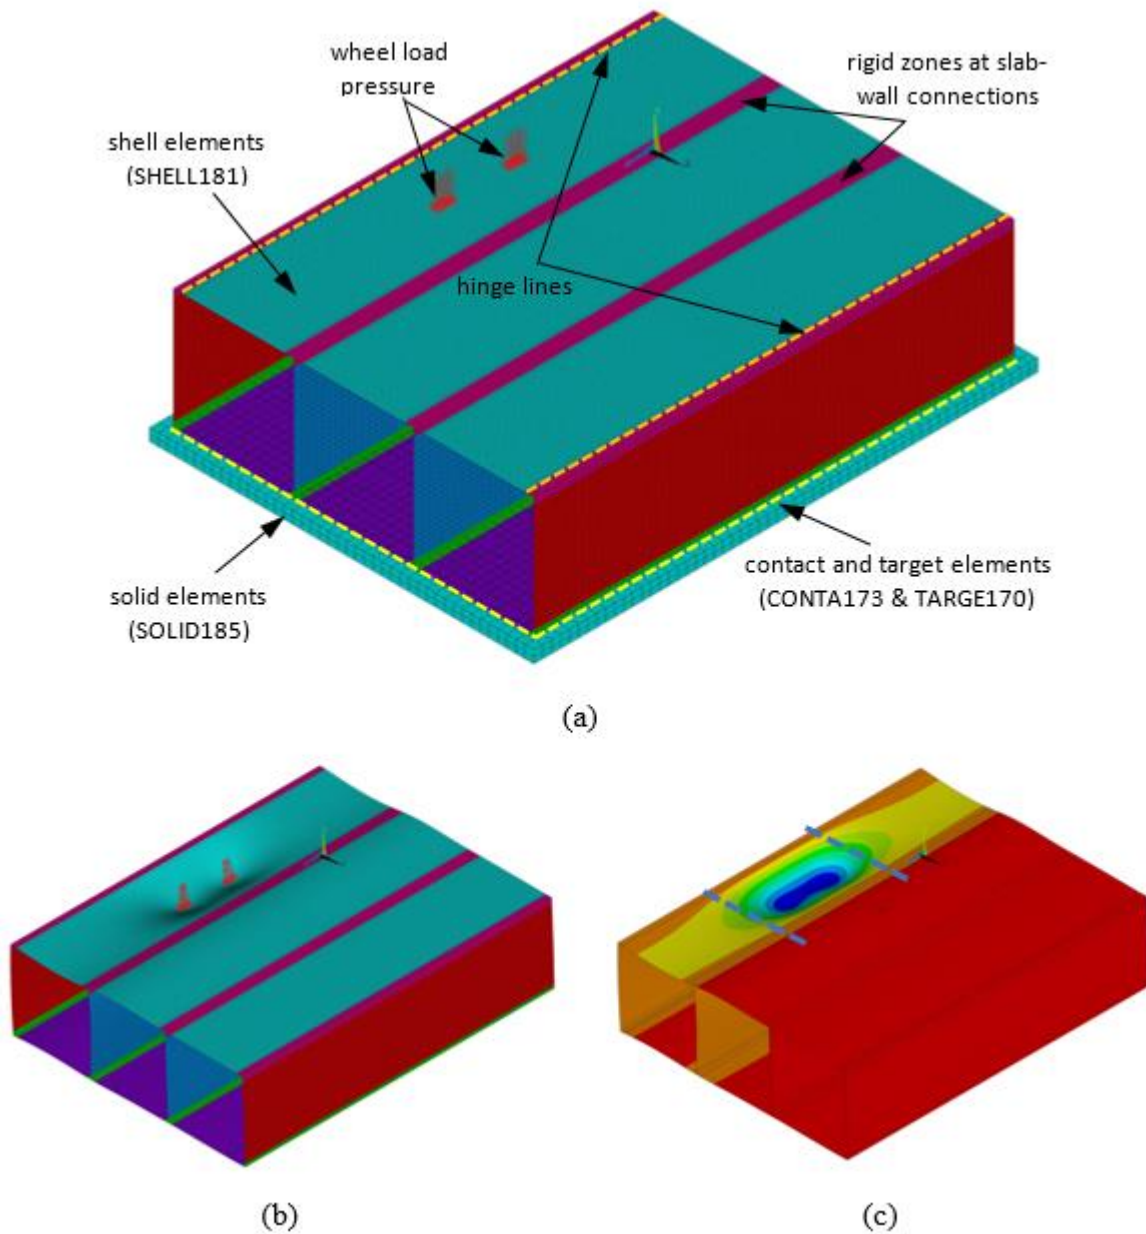

Figure 6. Solid element SOLID185 used to model soil subgrade [28]

It should be noted that the culvert's bottom slab shell elements and the top of the soil subgrade solid elements were not rigidly connected. Contact elements were used to serve as interface between both elements. CONTA173 contact element was used to model this effect. Figure 7 shows the geometric attributes of CONTA173. It should be noted that a target surface needs to be defined for CONTA173 elements. This was done using TARGE170, which represents the target surface in space. Based on the properties of the elements involved in this interface modeling, the culvert's slab was allowed to move upward with no resistance. However, downward movement was resisted by the subgrade soil. Figure 8 shows the deformed shape of the 3-barrel culvert discussed earlier. It can be seen that the first barrel is directly affected by the axle load on the soil more than the third barrel. Note that due to the large scaling of the deformations, the bottom slab appears to sink into the soil.

Figure 7. Contact element CONTA173 used to bottom slab – subgrade interaction [28]

Figure 8. Deformation of a 3-barrel culvert showing interaction between bottom slab and soil subgrade

Shell elements are typically positioned at the midsection of the structural plate they represent (e.g., wall or slab), which means that an overlap exists at these joints. In this study, the wall-slab joint was modeled following the same method described in detail in LTRC Report 593 [1]. To model the offsets of the top and bottom slabs and the walls connected to them, rigid elements were used for the distance from the centers of the wall or slab to a point at the face of the member (i.e., half the slab or wall thickness). In the case of haunches, these haunches added to the rigidity of the connections and further increased the overlap between the slabs and the walls. Therefore, it was also assumed that the rigid element section extended beyond the aforementioned half slab or half wall thickness by one-half of the haunch length due to the presence of additional concrete thickness. These rigid areas are shown in Figure 4-a for the top corner location. The same is also true for bottom connections, albeit without a haunch. Because of the lack of negative moment resistance at the top outer corners, a hinge was assumed along the length of the culvert transversely, as can be seen in Figure 9. All other joints are capable of resisting bending moments; therefore, full continuity was assumed at these joints.

Figure 9. Typical wall- slab connection details in FE models

Loading of 3D Model

The following loads were applied on the 3D models:

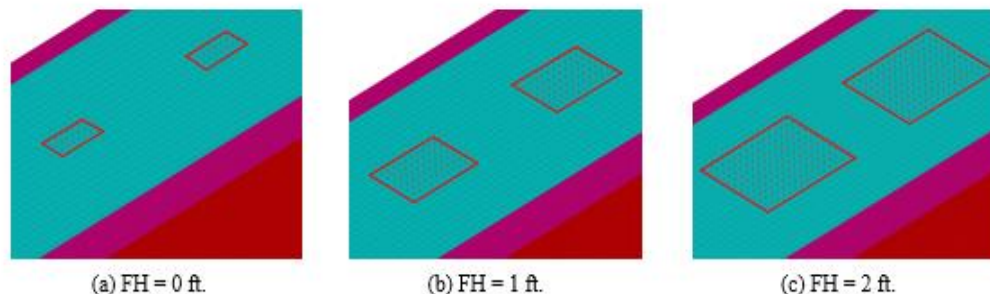

- Self-weight of culvert concrete slabs and walls
- Earth fill weight over the top slab
- Wearing surface above the earth fill
- Wheel loads

Densities of 150 pcf and 120 pcf were used in calculating the self-weight for concrete and earth fill weight, respectively. A 29 psf was assumed for the wearing surface. The self-weight was applied in the first load step of the analysis as a gravity load using ACCEL command in ANSYS. Earth fill weight and wearing surface were applied as surface pressures over the entire top slab area. Wheel loads were also applied as a surface pressure on the top slab; however, they were only applied over a determined area based on the attenuation of wheel pressure through the earth fill. Figure 10 shows three cases of wheel pressure on the top slab of a 1-barrel culvert. The three cases represent earth fill heights equal to 0 ft., 1 ft., and 2 ft. As seen in the figure, the area of the top slab subjected to the attenuated wheel load pressure increases with the fill depth. For $FH=0$ ft, the area is equal to the contact area of the wheel, which is taken equal to 10 in. x 20 in. according to AASHTO-LRFD BDS [5]. It was assumed that wheel load was distributed through fill heights greater than 0 ft. at a slope of 2:1.

The 2:1 slope assumption is based on established information in the literature. As pressure passes from the tire, it spreads slightly in the pavement structure [29]. Once through the pavement, the pressure further spreads and attenuates through the cover soil [30]. Upon

reaching the culvert surface, the load transfers through the top slab. Moreover, AASHTO-LRFD BDS define the stress distribution based on fill depths less or greater than 2 ft. (0.6 m.), while this study is concerned with fill depths less than 2 ft. (0.6 m.). The 1992 AASHTO specifications promulgate a distribution width (B) as a function of the effective span length. This was updated in 2007 for the mobilization of positive and negative moments. However, the AASHTO guidelines greatly underestimate actual soil pressures [29; 31-33]. Accordingly, the 2:1 method was used in these analyses. This is an empirical approach based on the assumption that the area over which the load acts increases in a systematic way with depth. For rectangles of 20 in. and 10 in., the pressure at the surface decreases by approximately 72% at a depth of 1 ft. To verify the 2:1 method, the same computations were made using the Boussinesq Theory for a rectangularly loaded area. Boussinesq developed equations of the state of stress within a homogeneous, isotropic, linearly elastic half-space for a point load [34]. Newmark [35] derived the equation for the vertical stress under the corner of a uniformly loaded rectangular area. The average stress dissipation at 1 ft. of fill depth is approximately 71% of the applied surface pressure. Similar computations were made for a depth of 2 ft. Both methods result in similar approximate stress distributions. As a result, the 2:1 method was implemented in the numerical simulations conducted in this study.

Figure 10. Wheel load pressure on top slab for different fill heights.

It should be noted that the meshing of the top slab was adjusted to make sure that the element dimensions fit the wheel pressure area exactly to avoid any unnecessary approximations due to pressure value adjustment, pressure area adjustment or both. This was achieved by defining areas before meshing that match exact dimensions of the wheel pressure area.

After determining the area affected by the wheel load pressure, this area was swept in the traffic direction to determine the maximum load effects for shear forces, positive and negative moments. This sweeping was necessary, as the critical wheel position cases for

shear are typically not the same as that for moments. Furthermore, the positions for the positive and negative moments also vary. Therefore, the wheel pressure was moved one element dimension at a time until the wheel pressure area exited the culvert at the other end. The number of wheel load positions in the traffic direction varied based on the culvert dimensions and fill height, which determines the size of the pressure area, as discussed earlier.

As required by AASHTO-LRFD BDS, both HL-93 design truck and design tandem were considered. Even though the tandem axle weight (25 kip) is less than that of the truck's axle weight (32 kip), its spacing is much smaller (4 ft. vs. 14 ft.), and therefore had to be considered in all analyzed cases. Figure 12 shows the case of a small culvert (6 ft.) with a design truck axle being swept across it. It is clear from the figure that a second axle with a 14 ft. spacing would not fit on a single barrel, nor on both barrels, for a negative moment case (i.e., one axle on each barrel). Figure 12 shows the case of a wide culvert (11 ft.) that would only fit one design truck axle. However, neither two nor three tandem axles can easily fit on one of the barrels.

Figure 11. Wheel load pressure on top slab (case of truck axle)

Details of 2D models

As stated earlier, engineers typically analyze culverts using 2D models for design and load rating. 2D models are easier to build and provide quick, direct answers to the user, unlike 3D models, which require advanced knowledge of the finite element method and a significant amount of post processing. By definition, 2D models do not represent the third dimension and are therefore considered an approximation of the exact behavior. The main source of approximation is the extent of the culvert transversely (perpendicular to traffic) that contributes to the resistance of the axle loads (see Figure 4-c). Hence, the goal of this study is to develop expressions for the equivalent width formula that provides acceptable accuracy over a wide range of culvert configurations and straining actions.

The 2D model in this study was built using BEAM188 element from the ANSYS element library. BEAM188 is based on Timoshenko's beam theory, which is suitable for slender to moderately thick beams. With three translation DOFs in the x , y , and z directions at each of

its two nodes, BEAM188 is capable of representing flexure, shear, and axial behavior. Figure 13 shows the geometric attributes of BEAM188. The element allows for the defining standard as well as general cross-sectional properties, including the orientation of the cross section in relation to the longitudinal axis of the element.

Figure 13. Beam element BEAM188 used to model culverts in 2D [28]

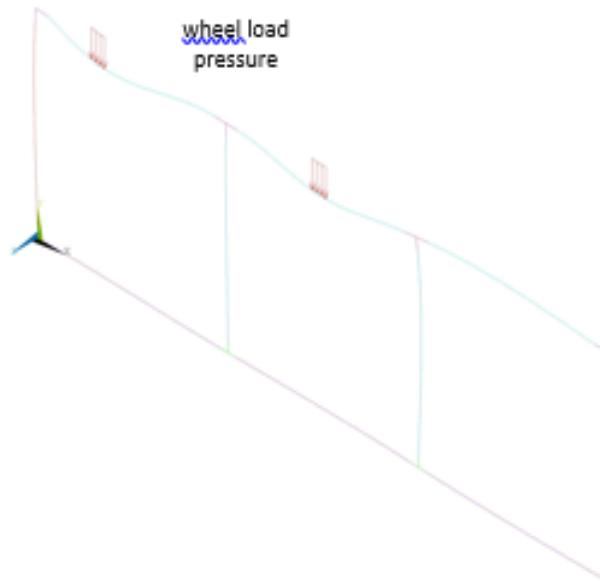

Error! Reference source not found. shows one of the 2D models for the case of a 3-barrel culvert ($S = 12$ ft.). In **Error! Reference source not found.**-a, the boundary conditions of the model are shown, including the hinge condition at the outside corners of the top slab, to reflect the lack of negative moment reinforcement. It should be noted that out-of-plane boundary conditions have been added to the model to ensure stability, but these are not shown in the figure. **Error! Reference source not found.**-b shows the deformed shape of the model for the case of two axles of a design truck passing over the culvert— one axle on the first barrel and the other on the second barrel.

Extraction of Results

Extracting the results is a major step in the analysis process. Identifying critical sections in 3D models is not always straightforward, as maximum effect has to be explored in two directions, longitudinally and transversely. Special scripts were written for this purpose, where straining actions (shear force and bending moment) were explored in a strip width nominally equal to 1 ft. until the maximum live load shear force and the maximum live load bending moment were found. Once this nominal strip was identified, the straining actions due to other load cases (self-weight, earth fill, and wearing surface) were also recorded for the same strip for the purpose of conducting the reliability study discussed later. It should be noted that for the shear forces and negative moments, the search for the critical strip was only done transversally since the maximum values of these straining actions happen at the face of the interior supports.

Figure 15 shows the straining actions considered in this study. As stated earlier, the exact location of the critical strips for these straining actions vary based on the truck type, position, and number of axles. The extracted results are:

V_L = shear force left of 1st interior wall

V_R = shear force right of 1st interior wall

M_{pE} = positive moment around 1st exterior midspan

M_{nL} = negative moment left of 1st interior wall

M_{nR} = negative moment right of 1st interior wall

M_{pI} = positive moment around 1st interior midspan

Figure 15. Straining actions extracted in this study

Mesh sensitivity study

As an approximate analysis method, the accuracy of FEM results is a function of several factors, including the mesh size. In addition to the possibility of missing critical stress locations if a coarse mesh size is used, the FEM approximation of the displacement field may also diverge further from the exact one. Therefore, choosing an appropriate mesh size is one of the important factors that need to be investigated before settling on a model. Typically, a mesh sensitivity study is conducted in which the element size is varied, and extracted results are compared. An acceptable mesh size is one where a mesh with smaller element sizes does not provide additional accuracy to the results (i.e., results have converged to the exact answer).

In this study, a single barrel case was investigated using five target element sizes: 2 in., 3 in., 4 in., 5 in., and 6 in. The models can be seen in Figure 16.

Figure 16. FE meshes used in sensitivity study (1-barrel case, $S=10$ ft., $FH=0$ ft. – (a) 6 in., (b) 5 in., (c) 4 in., (d) 3 in., (e) 2 in.)

(c)

(d)

(e)

The maximum live load positive moment in the top slab was extracted from all these models and compared with the moment values from the smallest element size model, i.e., 2 in. It can be seen that a 6 in. model would introduce a mesh size accuracy error of about 3.5%. This mesh size accuracy error drops as the element size is reduced. The table also shows that a nominal element size of 3 in. is extremely close to that of a 2 in. element size model with a difference of about 0.3%. This means that the solution has almost converged. Therefore, it was deemed acceptable to use the 3 in. element size for all models in this study, especially since the number of elements, nodes, and degrees of freedom increases exponentially rather than linearly as the element size is reduced. Finally, this element size allows for averaging the results from four elements or five nodes when extracting the straining action results per foot, which is a good number of data points to obtain representative results.

Table 1. Sensitivity study results

Mesh Size	6 in.	5 in.	4 in.	3 in.	2 in.
M_{pE}^{LL} (lb.in./in.)	5463.5	5437.2	5323.5	5295.3	5277.8
$M_{pE}^{LL} / M_{pE-2in.}^{LL}$	1.035	1.030	1.009	1.003	1.000

Parametric Study

Four parameters were considered in developing a suite of culverts that covers a wide range of configurations representing the current inventory. These parameters are:

- Concrete Compressive Strength, f'_c – It is known that the concrete elastic modulus (E_c) is directly related to its compressive strength. Therefore, it is clear that f'_c is directly related to the stiffness of the culvert's structural elements, which will be investigated to study its effect of the results.
- Number of Barrels, NB – The straining actions (shear forces and bending moments) developing in box culverts vary based on the number of barrels, especially for the DOTD standard detail with the hinged behavior at the outside corners. For example, the top slab behaves almost like a simply supported beam in a 1-barrel configuration. For 2- and 3-barrel configurations, the top slab is a continuous one on at least one side, which affects how the straining actions are distributed.
- Top Slab Thickness, t_s – The other parameter that affects a structural member's stiffness is its dimension. Even though DOTD standard culvert details call for specific slab and wall thicknesses, (t_s) was varied as one of the parameters in this study. Wall thicknesses (t_w) were taken equal to the standard detail values. Varying t_w and t_s at the same time would not cause the intended effect of varying the relative stiffness of the culvert's members.
- Fill Height, FH – The depth of the fill height (FH) determines the extent of the area affected by the wheel load pressure. Therefore, FH is considered in this study.
- Culvert Barrel Span Length, S – The literature shows that the width of the top slab affected by wheel loads is affected by the ratio of the distance from the wheel load to the closest support (a) and to the barrel span length (S). As discussed earlier, the axle position will be swept over the culvert, i.e., a is varied. Therefore, considering S as one of the parameters is necessary. Furthermore, the barrel span length also determines how many axles are on one or two barrels.

Based on this information, a range was identified for each of the aforementioned parameters. Table 2 lists the range of parameters considered in this study, which includes three f'_c values, three t_s values, three FH values, and seven S values. This translates to $3 \times 3 \times 3 \times 7 = 189$ cases for each number of barrel configuration. Initially, the 1-barrel culvert case was analyzed to study the effect of each of the parameters. Later, the number of cases for the 2- and 3-barrel culvert configurations are further discussed. The culverts included in the parametric study were designated based on the parameter values for each case. For example, B2W8H8ST8WT8H2C4 is a case with 2 barrels (2B), an 8 ft. barrel width (W), an 8 ft.

barrel height (H), an 8 in. slab thickness (ST), an 8 in. wall thickness (WT), a 1 ft. fill height (H), and a 4000 psi concrete compressive strength (FC). Table D1, Table D2, and Table D3 list all the cases considered in this study.

Table 2. Range of parameters considered in this study

Parameter	Range
Concrete Compressive Strength f'_c (psi)	3,000; 4,000; 5,000
Number of Barrels, NB	1; 2; 3
Top Slab Thickness, t_s (in.)	$t_s^{\text{standard}} - 1$; t_s^{standard} ; $t_s^{\text{standard}} + 1$
Fill Height, FH (ft.)	0; 1; 2

Reliability Assessment

Analysis models can only be implemented in design code provisions after conducting a thorough reliability investigation to ensure that they conform to acceptable AASHTO-LRFD safety levels. This reliability study is essential to overcome implementation barriers by conducting a comprehensive study that builds on the current provisions and is informed by historical provisions. This ensures that any proposed provisions provide adequate safety levels. Safety levels are typically presented in the form of a reliability index (β) that can be easily translated into a probability of failure (P_f) or probability of exceeding a certain design criterion according to the following equation:

$$P_f = \Phi(-\beta) \quad [4]$$

In this study, the focus will be on the *Strength I* limit state that typically controls the design and load rating of CIP-RC box culverts. Established procedures were based on principles of structural reliability similar to those used in the calibration of AASHTO's bridge design specifications [36], specifications for horizontally curved steel girder bridges [37], and the LRFR bridge evaluation manual [38; 39]. These procedures were successfully used by the PI for the calibration of shear strengthening using FRP provisions through NCHRP Project 12-75 [40]. Figure 17 shows the overall process of the reliability analysis.

Figure 17. Overall process of the reliability analysis

The basic form of the limit state function (g) for reliability analysis is:

$$g = R - Q \geq 0 \quad [5]$$

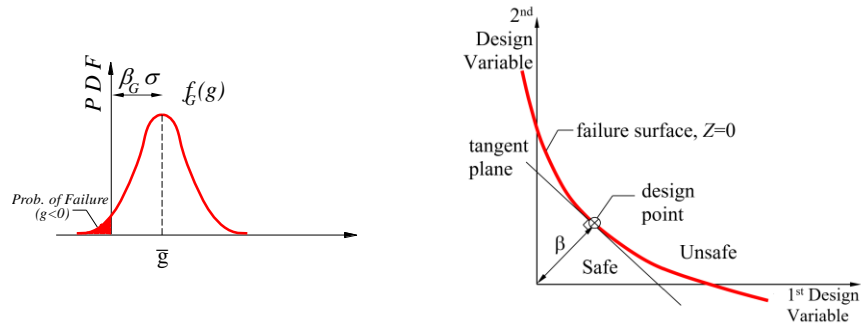

At the member level, R is the uncertain structural resistance and Q is the random load effects. The uncertain structural resistance (R) can be expressed as a function of the nominal resistance as obtained from the proposed design equations or analysis models (R_n) and the uncertainties stemming from material properties (M), fabrication (F), and a professional factor of design or analysis model (P). In addition to the randomness in load effects, as well as the uncertainties due to the use of approximate live load distribution equations, the derivation of resistance factors considered these three sources of uncertainty in the resistance models described below.

The limit state function for strength design at the member level, $g_{member}()$ reflect the aforementioned random variables on both the resistance and load sides of the design equation, including Q_{DC} , Q_{DW} , Q_{LL+IM} , and ξ_{LLDF} that represent the load demands due to component dead loads, wearing surface, live plus impact, and the accuracy of AASHTO live load distribution factor formulas, respectively.

Each bridge within the selected design space was evaluated for each design limit state. The probability of failure expressed by the reliability index (β) was determined (see Figure 18-a for the relationship between β and the probability of failure (P_f)). The First Order Reliability Method (FORM) was used in this study to find the design point, which is defined as the closest point on the failure surface ($g = 0$) to the origin of the standard forms domain of the random variables (see Figure 18-b). The reliability index (β) is then calculated in FORM in the standard form ($Z_i = (X_i - \mu_X)/\sigma_X$) domain where, μ_X and σ_X are the mean and standard deviation for each random variable (X_i) in its original domain. β values estimated using this procedure will be compared to pre-determined target reliability level (β_T), which is typically equal to 3.5 for calibrating strength limit states. For comparison purposes, β values resulting from existing provisions in AASHTO-LRFD BDS [5] were also considered. If the evaluated β did not meet β_T for a given limit state, the live load distribution formula was adjusted. The

culvert cases used in the parametric study discussed earlier will be used as the design space for the reliability study.

(a) PDF of limit state function, $g(\)$ (b) Determining β using FORM

Resistance Models

The resistance models used in this study were flexure and shear resistance, which are well established in the literature. For example, the shear resistance of the top slab was only due to the concrete contribution (V_c), which, according to AASHTO-LRFD BDS, is given by the following equation:

$$V_c = 0.0316\beta_v\sqrt{f'_c}b_vd_v \quad [6]$$

Where, b_v and d_v are the web width and effective depth of the cross section; f'_c is the concrete compressive strength; and β_v is a factor taken equal to 2.0 for non-prestressed members, with a depth less than 16.0 in. according to AASHTO-LRFD BDS 5.7.3.4.1. No stirrups are typically provided in slabs; therefore, no shear reinforcement contribution was considered. The following sections present the variabilities used in the current study. For each parameter treated as a random variable, a bias, coefficient of variation, and distribution type are given. For any random variable (X), the bias (λ_X) is defined as the ratio between of the mean value (μ_X) of the parameter it represents to its nominal value (X_n). The coefficient of variation ($COV(X)$) is the ratio between the standard deviation (σ_X) and the mean value (μ_X).

$$\lambda_X = \frac{\mu_X}{X_n} \quad [7]$$

$$COV(X) = \frac{\sigma_X}{\mu_X} \quad [8]$$

As seen from Equation [6], resistance models typically involve several parameters for which statistical parameters are needed. Concrete material statistical parameters have been derived in earlier studies using large datasets. Therefore, in this project, existing information was utilized. As an example, Nowak and Szerszen [41] proposed an equation for the bias factor of concrete compressive strength ($\lambda_{f'_c}$) as a function of the nominal concrete compressive strength (f'_c) and a COV equal to 10%. A literature review was performed to determine the statistical parameters and distribution types of all the material random variables. The fabrication factor (F) accounts for uncertainties in measured dimensions and other fabrication related parameters. A review of the literature indicates the information provided in Table 3 regarding certain fabrication related random variables.

Table 3. Material and fabrication random variables parameters [41-43]

Variable	Bias, λ	COV, %	Distribution Type
Concrete strength, f'_c	varies	10.0	Normal or lognormal
Dimensions (h, d, b)	1.00 – 1.03	0.5 – 7.0	Normal
Area of reinforcement	1.00	0.0 – 4.0	Normal

The professional factor accounts for the uncertainty in the prediction model. Determining this factor typically involves the compilation of a database of test results conducted on specimens failing with the desired mode of failure. Using the predicted ($Q_{pred.}$) and experimentally obtained resistance ($Q_{exp.}$), the bias ($\lambda_p = \mu(Q_{exp.}/Q_{pred.})$) and the coefficient of variation ($COV_p = \sigma(Q_{exp.}/Q_{pred.})/\mu(Q_{exp.}/Q_{pred.})$) for the professional factor will be determined. The modes of failure considered in this study were fundamental (flexure and shear), and can therefore be found in the literature. The aforementioned factors translate to the following biases and coefficients of variation for reinforced concrete members [36].

Table 4. Material and fabrication random variables parameters [36]

Variable	Material & Fabrication, MF		Professional Factor, P		Resistance Model, R	
	Bias, λ	COV (%)	Bias, λ	COV (%)	Bias, λ	COV (%)
Flexure, M	1.120	0.120	1.020	0.060	1.140	0.130
Shear, V	1.165	0.135	1.200	0.100	1.400	0.170

Load Models

The load, or demand, side (Q) of any limit state function is also represented as a random variable. Load models are typically determined based on field studies to determine the statistical characteristics of applied loads. Dead loads due to structural components (DC), wearing surface (DW), and highway truck loads (LL) can be easily found in the literature [44], which are listed in Table 5. In this study, the applicable load models from the literature was used. These include the dead loads, DC and DW. It should be noted that the live load model listed in Table 5 is for bridge girder design; in other words, it represents the statistics of the gross vehicle weight of highway trucks, which encompasses all axles of the trucks traveling over bridges. This information is determined by analyzing Weigh-In-Motion (WIM) data from several stations. Culvert design is controlled by one or two axles of a single truck. Therefore, another live load model is needed for the reliability analysis of culvert design.

Table 5. Bias and COV for load effects [45-48]

Variables	Statistical properties			Reference
	Bias λ	Coefficient of Variation CV	PDF	
Deck Dead Load	1.05	0.10	Normal	[45; 46]
Soil Self Weight	1.00	0.03	Normal	[47; 48]
Wearing Surface	1.00	0.25	Normal	[45; 46]
Live Load	Varies	Varies	Extreme Type I	[49]; current study

LTRC Project 07-2P characterized and developed truck load spectra and growth factors for current and future pavement design practices in Louisiana [49]. The truck load spectra was used to determine the statistical load model for individual truck axles representative of Louisiana highway truck traffic. LTRC Report 445 [49] provides histograms of the truck axles with different configurations and truck traffic classifications (TTC). For the purpose of the current study, the focus was on TTC 1 truck classification, which is for a major single-trailer route that is typically associated with principal arteries (e.g., interstate, defense, freeways, and expressways). Within this truck classification, two axle configurations were considered: a single axle and a tandem axle. Figure 19 and Figure 20 show the axle load spectra for the two axle configurations considered in this study.

Figure 19. Single axle load spectrum for combined vehicle classes for TTC 1 [49]

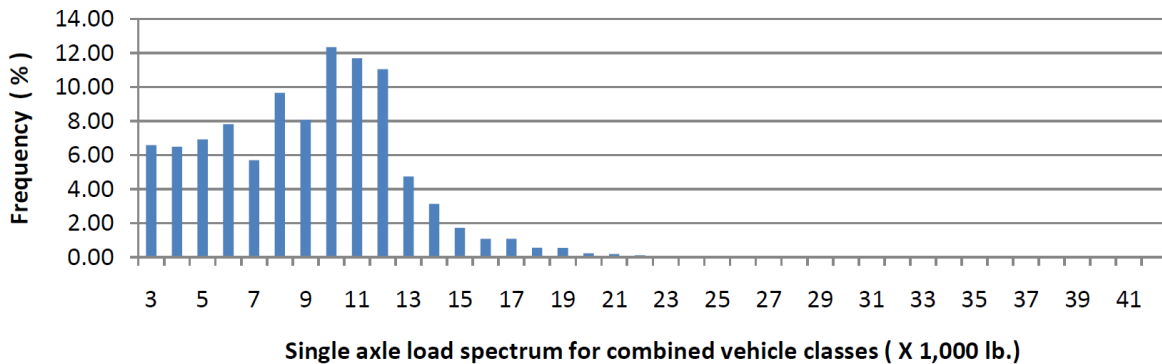

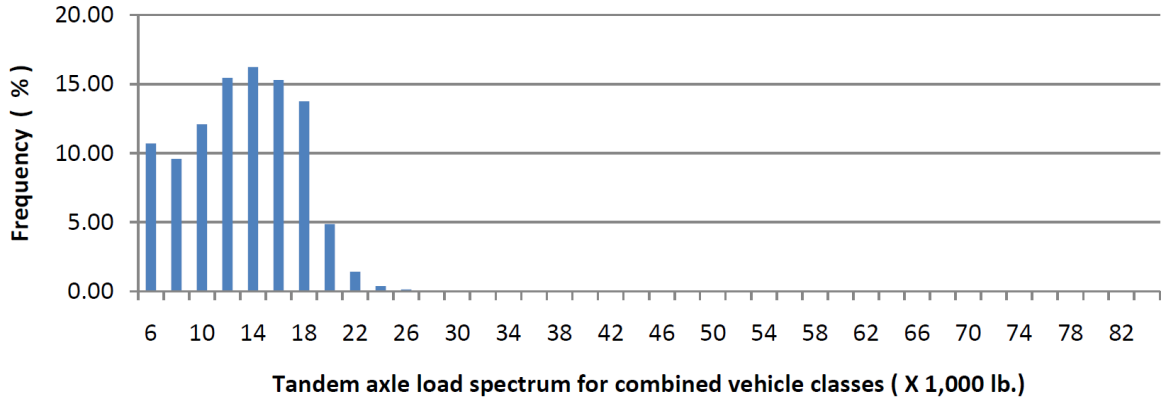

Figure 20. Tandem axle load spectrum for combined vehicle classes for TTC 1 [49]

These spectra were analyzed statistically to determine the most suitable distribution type to establish an appropriate load model for culverts. Figure 21-a shows the histogram for the case of TTC 1 single axle load spectrum, which is fitted using a bimodal distribution selected as a mixture of two normal (Gaussian) distributions. It should be noted that distribution had to be scaled to maintain a 100% probability if all axle loads were considered, due to the truncations to eliminate lower axle loads in the WIM data. Figure 21-b shows a comparison between the selected bimodal distribution and a fitted normal distribution. It can be seen that the normal distribution is not a reasonable fit for the histogram data. This observation was confirmed via a Chi-square statistical test that showed that the bimodal distribution is acceptable for a 5% significance level [50]. Figure 22-a and 22-b show the same results for the TTC 1 tandem axle load spectrum.

Figure 21. Selected bimodal distribution for single axle load spectrum for combined vehicle classes for TTC 1

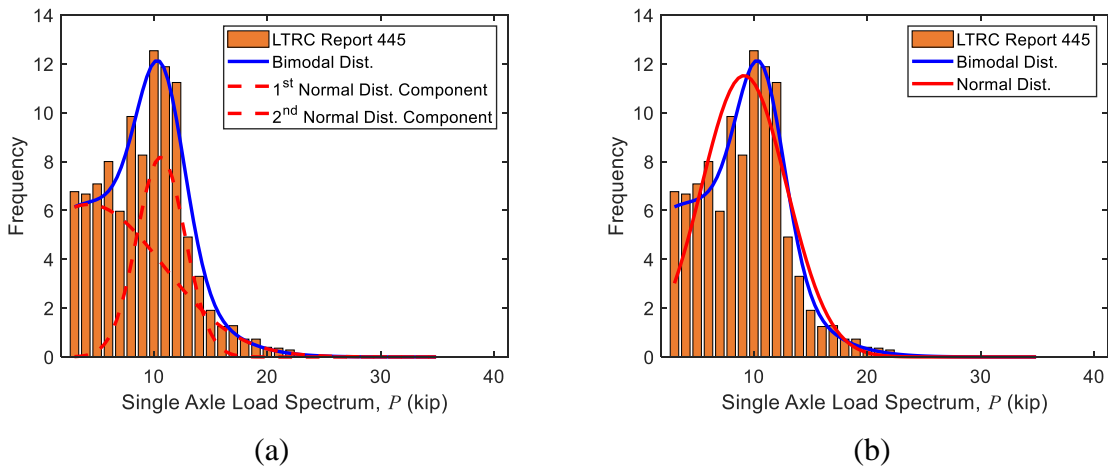

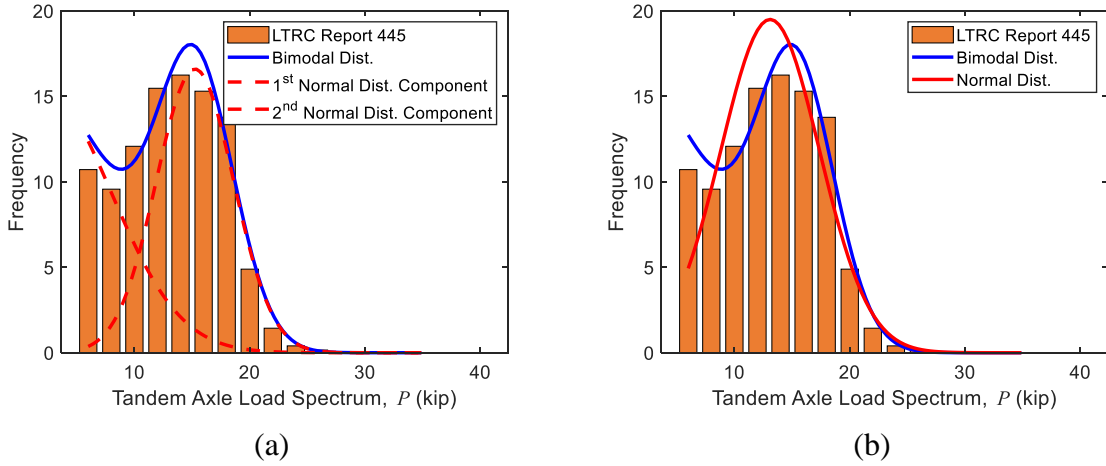

Figure 22. Selected bimodal distribution for tandem axle load spectrum for combined vehicle classes for TTC 1

It should be noted that the WIM data was collected over a limited time period of three years, between 2004 and 2006. AASHTO-LRFD BDS targets a 75-year design life. Therefore, the established statistical characteristics for the WIM monitoring period were extrapolated over a 75-year design period according to the Extreme Value Theory (EVT), which is used to quantify tail behavior of an independent continuous random variable. For this study, extreme values are the largest observations sampled with size n from a population. According to EVT, the probability distribution of the largest extreme value (M_n) extracted from the sample has a limiting distribution that converges the Generalized Extreme Value ($G(x)$) distribution:

$$\lim_{n \rightarrow \infty} Pr \left(\frac{M_n - a_n}{b_n} < x \right) \rightarrow G(x) \quad [9]$$

Where, a_n and b_n are normalizing constants [51; 52]. The Generalized Extreme Value distribution is a distribution family that has three forms: Type I (Gumbel), Type II (Frechet), and Type III (Weibull). Three parameters characterize the Generalized Extreme Value distribution, namely a location parameter (u), a scale parameter (α), and a shape parameter (ξ), as given in Equation [10]. As explained later, the cumulative distribution function (CDF) for Type I distribution (i.e., Gumbel distribution, with $\xi = 0$) is of interest in this study.

$$G_X(x) = \exp \left(- \left[1 + \xi \left(\frac{x - \mu}{\alpha} \right) \right]^{-\frac{1}{\xi}} \right) \quad [10]$$

The cumulative distribution function of the extrapolated extreme value of axle loads for 75-year return period is expressed by:

$$\begin{aligned}
F_X^{75 \text{ yrs}}(x) &= [F_X^{3 \text{ yrs}}(x)]^N & [11] \\
&= \exp(-\exp(-\frac{x - u_n}{\alpha_n}))
\end{aligned}$$

Where, α_n is the scale parameter and u_n is the location parameter of 75-year extrapolated extreme axle loads. For a Gumbel distribution, the scale parameter over a 75-year return period remains the same. However, the location parameter can be estimated as:

$$u_n = u + \alpha \text{Ln } N \quad [12]$$

Where, N is the number of expected extreme events in a 75-year return period. The mean maximum value of the extrapolated data (μ_L) and standard deviation of mean maximum value (σ_L) can be determined using the following equations [51].

$$\mu_L = u_n + \gamma \alpha_n \quad [13]$$

$$\sigma_L = \frac{\pi}{\sqrt{6}} \alpha_n \quad [14]$$

Reliability Evaluation

Based on the aforementioned resistance and load statistical models, a reliability study was conducted for the shear and flexure strength limit states. Using the statistical characteristics for the sources of uncertainties described earlier (professional factor, P ; material variabilities, M ; fabrication tolerances, F) on the resistance side, as well as the uncertainties associated with dead and live loads published in the literature, and in addition to the uncertainties inherent in the live load distribution equation, it is possible to establish a limit state function for calculating the reliability index (β). The limit state function for strength design (*Strength I* limit state— $g_{Str. I}$) is given in Equation [15] and reflects the aforementioned random variables on both the resistance and load sides of the design equation.

$$g_{Str. I} = R_R - (Q_{DC} + Q_{EF} + Q_{DW} + \xi_{LLDF} Q_{LL+IM}) \quad [15]$$

Where, R_R is the random variable representing the resistance, and Q_{DC} , Q_{EF} , Q_{DW} , and Q_{LL+IM} are the random variables representing the load demands due to component dead loads, earth fill, wearing surface dead loads, and live load plus impact, respectively. The random variable (ξ_{LLDF}) was also included to account for the uncertainties introduced due to

the use of empirical live load distribution formulas that are typically used in design. Its bias ($\lambda_{\xi_{LLDF}}$) is taken from the results of the parametric study discussed earlier. The reliability index was evaluated using Theory of Reliability to obtain a reliability index (β) for each culvert design in the design space. Table 3 and Table 5 list the bias and coefficient of variation for load effects used in the study.

Discussion of Results

In this section, results obtained from the finite element analyses of a parametric study are presented. The parameters considered in the study are first discussed. Results from 3D and 2D models for each culvert and comparisons of both sets of results are investigated. Finally, a live load distribution formula is developed based on all the results obtained from the parametric study.

Investigation of Parameter Effects on 2D Model Accuracy

All results from the analyses performed in this study can be found in Appendix B (Table E1 through Table E12). The effect of each of the considered parameters are first analyzed in this section. To investigate the effect of each of the parameters described in the previous section, the 1-barrel case is considered. (Table E1, Table E4, Table E7, and Table E10). The live load distribution formula is adopted in AASHTO-LRFD BDS [5] in which the wheel load is distributed in two directions. In the direction parallel to the span, the axle load is distributed over a width on the top slab (E_{span}) equal to:

$$E_{span} = L_T + LLDF(H) \quad [16]$$

Where, L_T is the length of the tire contact area (10 in.), $LLDF$ is the live load distribution factor taken as 1.15, and H is the fill depth. In the direction perpendicular to the span, the width of the wheel pressure area (E) is:

$$E = 96 + 1.44 S \quad [17]$$

Where, S is the barrel's clear span length in feet; however, the result is in inches.

The results will be presented in the form of a ratio between the 2D and 3D straining actions. This ratio is often referred to as *bias* (λ):

$$\lambda = \frac{R_n^{2D}}{R_n^{3D}} \quad [18]$$

Where, R_n^{2D} and R_n^{3D} are the straining actions extracted from the 2D and 3D models, respectively. The effect of each parameter was investigated separately by plotting the average

bias value (λ_{avg}) and coefficient of variation (COV) as an indication of the scatter of the ability of Equation [17] to predict the culvert response accurately. First, these results are presented in the form of histograms that show the distribution of λ . The variation of λ_{avg} with respect to key parameters are then be plotted to identify any trends to help assess existing live load distribution formulas and develop a new formula. Similar plots are also presented for the coefficient of variation (COV) for each straining action.

Effect of Barrel Span Length, S

Figure 23 shows the histograms of the bias (λ) for all straining actions extracted from the models analyzed in this study. The histograms are classified based on the barrel span length (S), for which seven values were considered in the parametric study. Each of the histograms show a vertical dashed line, which is the average of all bias values for each group of cases. It is clear that all bias values have an increasing trend from lower to higher S values, albeit more pronounced for positive moment biases than shear and negative moment biases. This is expected, as the wheel area distribution width is known to be larger for positive moments where the critical load case is typically when the wheel is close to midspan, as opposed to the other cases where the critical load case is controlled by wheel load positions close to the supporting walls, especially for shear cases. The proximity of the wheel load to the wall does not allow the top slab to distribute wheel pressure effectively. In other words, even though Equation [17] is a function of the span length (S), it seems it does not reflect the full ability of the top slab to distribute wheel load pressure.

The trends of the biases and the COV are shown in detail in Figure 24 through Figure 27. Figure 25-a and Figure 27-a show a clear increasing trend ($\lambda \gg 1.0$) that is conservative by at about 40% as a minimum. The conservatism in the exterior barrel positive moment reaches almost 80% ($\lambda \approx 1.80$), while only 55% ($\lambda \approx 1.55$) was observed for the interior barrel positive moment. This is due to the continuity of the interior barrel on both ends, which stiffens the top slab more than in the case of the exterior barrel, and hence reduces its ability to distribute wheel loads farther. For critical shear forces bias (λ_V), Figure 24-a also shows an increasing trend; however, the bias values are unconservative ($\lambda < 1.0$). This implies that even with the conservatism injected in positive moment biases, the shear forces are not as would be expected. As a result, developing one distribution formula that fits both shear forces and positive bending moments will be challenging. The same can be observed in Figure 26-a for the negative moment bias (λ_{M_n}), which increased for larger spans as a result of the ability to fit a second axle that is positioned closer to midspan, thus providing the slab with more room to distribute the wheel load pressure.

The *COV* shown in the figures reflect a range of 15%-25% for shear force bias ($COV(V)$), 8%–11% for exterior barrel positive moment bias ($COV(M_{pE})$), 4%–9% for negative moment bias ($COV(M_n)$), and 13%-18% for interior barrel positive moment bias ($COV(M_{pI})$).

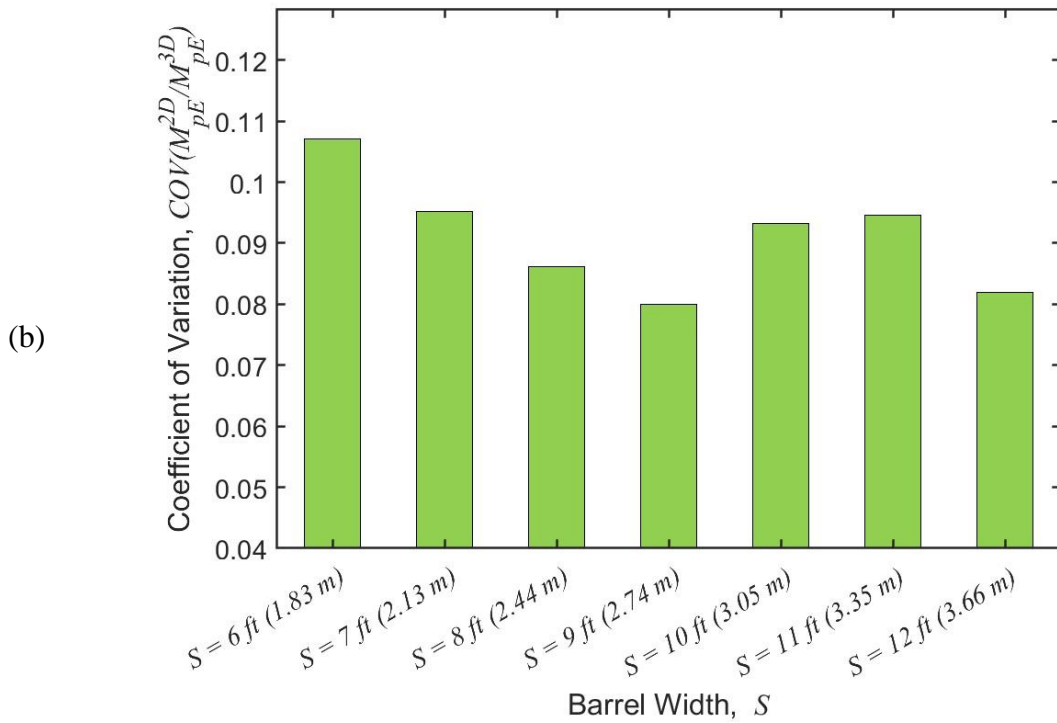

Figure 26. Trend of negative moment bias $\lambda_{Mn,avg}$ and COV vs. barrel span length, S

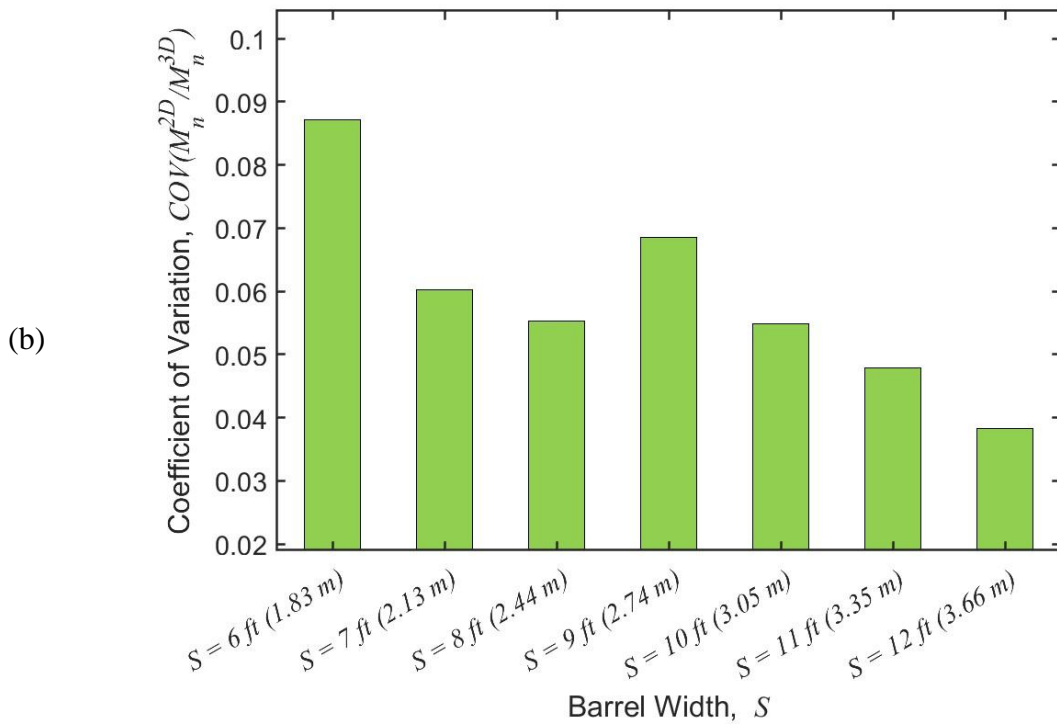

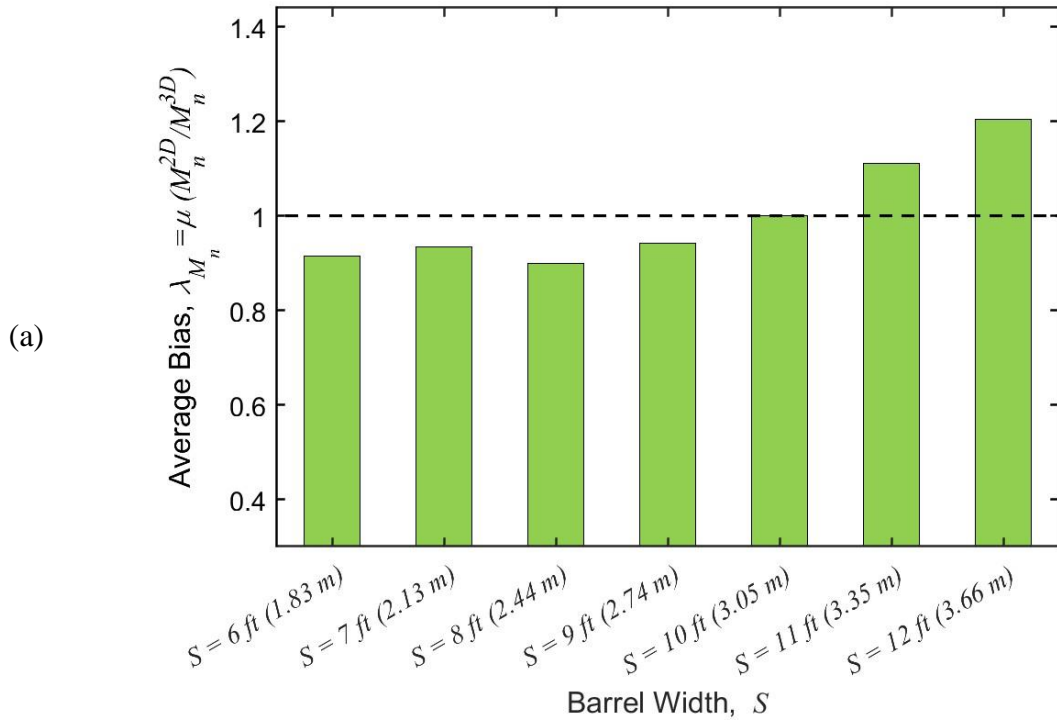

Figure 27. Trend of interior positive moment bias $\lambda_{M_{pl,avg}}$ and COV vs. barrel span length, S

Effect of Fill Height, FH

Figure 28 shows the histograms of the bias (λ) for all straining actions extracted from the models analyzed in this study. One can observe that shear forces (λ_V) appear to be affected by the fill height more than Equations [16] and [17] imply. The average bias ($\lambda_{V,avg}$) is substantially negative for $FH = 0$ ft., slightly negative for $FH = 1$ ft., and positive for $FH = 2$ ft. The trends of the shear bias and its COV are also shown in detail in Figure 29.

For positive bending moment bias ($\lambda_{M_{pE}}$) in the exterior barrel of culverts, Figure 23 shows that the bias is positive for all cases indicating conservatism in the range of 40% to 75% as can be seen in Figure 30-a. This is likely why many culverts struggle to pass load rating requirements. It should be noted that the scatter of the results increases with the increase in conservatism (see Figure 30-b). The negative moment bias values (λ_{M_n}) shown in Figure 31 are surprisingly on the mark, with bias values consistently around 1.0. Finally, Figure 32 shows the positive bending moment bias ($\lambda_{M_{pI}}$) in the interior barrel of culverts to have a conservative trend, like the positive bending moment in the exterior barrel. All cases show an increasing bias value indicating a conservatism inherent in Equations [16] and [17]. The reason for this conservatism is likely due to the fact that AASHTO-LRFD BDS formulas ignore the secondary distribution that the top slab introduces to the system, which is known to be a function of the barrel span length. Therefore, it appears that Equation [17] does not adequately reflect this secondary distribution.

Figure 32. Trend of interior positive moment bias $\lambda_{M_{pl,avg}}$ and COV vs. fill height

Effect of Culvert Concrete Compressive Strength, f'_c

Figure 33 shows the histograms of the bias (λ) for the shear force (V) and positive moment (M_{pE}) in 1-barrel cases. The histograms are shown for the concrete compressive strength (f'_c) values considered in the parametric study: 3000, 4000, and 5000 psi. It is clear that the concrete compressive strength (f'_c) does not affect the bias values nor does it affect the coefficient of variation, ($COV(\lambda_V)$). For statically indeterminate structures such as box culverts, the modulus of elasticity of concrete (E_c) typically affects the analysis results, and it is well known that E_c is proportional to concrete compressive strength (f'_c). Hence, f'_c was included in the investigated parameters. However, the reason why results were not affected is attributed to the fact that increasing/decreasing f'_c for elements of the culvert (slabs and walls) keeps the relative stiffness of these elements the same. This is confirmed for the positive moment (M_{pE}). Figure 34 and Figure 35 show plots of the bias (λ) and coefficient of variation trends ($COV(\lambda_V)$), which do not change for both internal forces extracted from the 1-barrel cases, namely V and M_{pE} .

Based on these results, it was concluded that f'_c is not a parameter that affects the development of internal forces in box culverts. Therefore, it was not included in the subsequent analysis for 2-barrel and 3-barrel cases.

Effect of Number of Barrels, N_B

The available data allows for investigating the effect of number of barrels on the accuracy of results. Figure 36 shows the histograms of the bias (λ) for all straining actions extracted for this study. Obviously, some straining actions are not available for models with all numbers of barrels. For example, the negative moment (M_n) bias is only available for barrels with continuous top slabs, namely 2- and 3-barrels. Similarly, the bias for positive moment in interior barrels (M_{pl}) is only available in 3-barrel cases. The figure shows that there is no strong correlation between the number of barrels and the bias of straining actions. This can be explained by the previously discussed secondary distribution behavior that mainly relies on the wheel load position relative to the span length. The number of barrels will be included in this study simply because it allows for investigating more straining actions often encountered in the design and load rating of culverts (i.e., negative moment [M_n] and positive moment in interior barrels [M_{pl}]). For completeness, Figure 37 through Figure 40 show plots of the bias (λ) and coefficient of variation trends ($COV(\lambda)$) for all straining actions.

Effect of Span to top slab thickness ratio, S/t_s

The final parameter discussed is the slab thickness. The S/t_s ratio was selected instead of an absolute thickness because the most important parameter is the top slab stiffness, which affects the ability of the slab to distribute wheel loads. The histograms are shown for different span to top slab thickness ratios (S/t_s), which were grouped into three ranges: $S/t_s \leq 10$, $10 < S/t_s \leq 12$, and $S/t_s > 12$. Figure 41 shows the histograms of the bias (λ) for the shear force (V) and positive moment (M_{pE}) in 1-barrel cases. The figure shows that there is a correlation between the S/t_s ratio and the bias values for both shear and positive bending moment, albeit not as pronounced as for fill height (FH) or span length (S). The difference in the average bias (λ) for the different ranges is approximately 10%, which is lower than the values obtained for the other parameters, which reached up to 40%. Consequently, it was concluded that the ratio S/t_s is not a major parameter to be included in the proposed formula since its inclusion would add complexity to the formula, with little improvement in the prediction accuracy. Figure 42 and Figure 43 show plots of the bias (λ) and coefficient of variation trends ($COV(\lambda)$), which do not change for both internal forces extracted from the 1-barrel cases, namely V and M_{pE} . Therefore, the slab thickness parameter was not considered in the 3-barrel cases of the parametric study.

Development of New Live Load Distribution Formula

Parameters included in New Live Load Distribution Formula

Based on the parametric study results, it was determined that the main parameters that directly affects the straining action results are:

- Fill Height, FH
- Barrel Span Length, S

In addition to these parameters, the axle gauge (distance between wheels in one axle) clearly influences the top slab area width engaged in the resistance of wheel loads, as can be seen in Figure 4-c. The developed equation is based on the AASHTO-LRFD BDS equations for wheel load distribution (Equations [16] and [17]). Only Equation [17] was considered in the development of the modified live load distribution formula. The reason the focus was on Equation [17] is that current wheel load distribution formulas do not reflect the secondary distribution of wheel loads in the transverse direction, as discussed in the previous section.

To address this aspect of wheel load distribution, the following formula was investigated.

$$E = 92 + 1.15 H + \eta S \quad [19]$$

Where, H is the fill height (in.), S is the barrel span length (in.), and η is coefficient that will be calibrated to achieve the best results. η -values ranging from 0.1 to 0.5 will be considered.

The three terms of the formula shown in Equation [19] reflect the outer distance between wheels, the additional width that the earth fill helps distribute the wheel load, and the ability of the top slab to distribute the wheel load beyond the extents of the earth pressure, respectively. The first term is the standard distance of a design axle ($0.5 \times 20'' + 6' \times 12''/'' + 0.5 \times 20'' = 92''$), while the second term is unchanged from AASHTO-LRFD BDS for the distribution in the direction parallel to the span length (AASHTO Eq. 4.6.2.10.2-2). Finally, the third term is a function of the span length as it is established in the literature that the ability of slabs to distribute non-uniform loads is a function of the distance from these loads to the closest support. For example, a load at mid-span would be distributed over a width equal to $0.5 S$. For the many load cases considered in this study, the maximum effect for each critical case differs from one straining action type to another. For example, maximum positive moments are generated from wheel positions close to midspan. Conversely, maximum shear forces are caused by wheel loads close to the support. This

complexity was investigated by varying the η parameter to identify a suitable value that covers as many straining actions as possible.

Calibration of Secondary Distribution Effect in New Live Load Distribution Formula

Figure 44 shows the histograms of the bias (λ) for all straining actions extracted from the models analyzed in this study using the proposed formula (Equation [19]) with five η values (0.1 – 0.5). It can be seen that the average bias (dashed lines in individual figures) varies with the change in the distribution width (E) in the perpendicular direction to the span. As stated earlier, this is expected because a wider E dimension reflects the ability of the slab to distribute wheel pressure beyond the projection of the axle wheel through the soil onto the top slab, i.e., secondary distribution. By studying these average bias values, it is obvious that for positive moments (M_{pE} and M_{pI}) the average bias value is greater than 1.0 for most considered η values, and that it is closest to 1.0 for a value of $\eta = 0.4$. As stated earlier, the critical positive moments occur due to wheel position around midspan. For shear forces and negative moments (V and M_n) the average bias values are all less than 1.0, reflecting that little secondary distribution takes place for the wheel positions causing these critical values, which is closer to the culvert walls supporting the top slab. This means that deriving one formula for all straining action types will correlate well with some straining actions, while being conservative/unconservative to others.

The trends of the biases and the COV are shown in detail in Figure 45 through Figure 48 for V , M_{pE} , M_n , and M_{pI} , respectively. Figure 45-a through Figure 48-a show a clear decreasing trend of the average bias for all extracted straining actions; however, a clear divide is noted for the positive moments (M_{pE} and M_{pI}) and from the shear and negative moment (V and M_n) with the former being mostly conservative ($\lambda > 1.80$) while the latter being unconservative ($\lambda < 1.80$). The consistency of the prediction accuracy can be assessed by studying the scatter in the bias (λ), i.e., $COV (R_n^{2D}/R_n^{3D})$. It is clear that the divide carries over to the scatter as well, with COV values in the single digit percentage for positive moments (M_{pE} and M_{pI}) predictions, whereas values close to 15% are observed for the shear and negative moment (V and M_n) predictions.

Based on these results, it was determined that while a value for $\eta = 0.4$ is more suitable for predicting positive moments (M_{pE} and M_{pI}), it injects a high level of unconservatism for the shear and negative moment (V and M_n) predictions. Therefore, a value of $\eta = 0.3$ is investigated in the following sections to assess its performance over a wide range of cases and in comparison with existing formulas, especially AASHTO-LRFD BDS.

Comparisons between Predictions using Proposed Formula and AASHTO-LRFD BDS

In this section, comparisons are conducted between the predictions of the proposed formula and AASHTO-LRFD BDS formulas for wheel pressure distribution. In addition to the formulas adopted in AASHTO-LRFD BDS, another set of comparisons is presented using the recommendations of LTRC Project 16-3ST, in which rigid links were recommended in 2D models to reflect the rigid nature of the slab-wall connections [1]. Figure 49 shows the histograms of the bias (λ) for all straining actions extracted from the models analyzed in this study considering the three different live load distribution formulas (LLDF): AASHTO-LRFD BDS, modified AASHTO-LRFD BDS, and proposed formula (Equation [19]) with η value equal to 0.3. It can be seen that the average bias (dashed lines in individual figures) is closer to unity for the proposed formula for the positive moments (M_{pE} and M_{pI}).

Furthermore, despite the lower bias values for the shear forces and negative moments V and M_n , it can be seen that the scatter is less when the proposed formula is used. These observations can be seen clearly in the comparisons of the bias (λ) and coefficient of variation (COV) in Figure 50 through Figure 53 for the biases of V , M_n , M_{pE} and M_{pI} , respectively. It is clear that the proposed formula results in coefficient of variations that are less than those obtained using AASHTO-LRFD BDS formula for all cases except for the bias for M_n , which is still close. As expected, the bias for shear forces and negative moments (V and M_n) are lower than 1.0, which is unconservative despite the lower scatter. This is due to the proposed formula emphasizing the positive moments (M_{pE} and M_{pI}). To remedy this deficiency, a multiplier coefficient can be used for the formula (ξ_{SA}) that reflects the type of straining action. In other words, ξ_{SA} would be equal to 1.0 for positive moments (M_{pE} and M_{pI}) and 0.6 for shear forces and negative moments (V and M_n).

Figure 49. Histogram of straining action bias obtained using different LLDF formulas

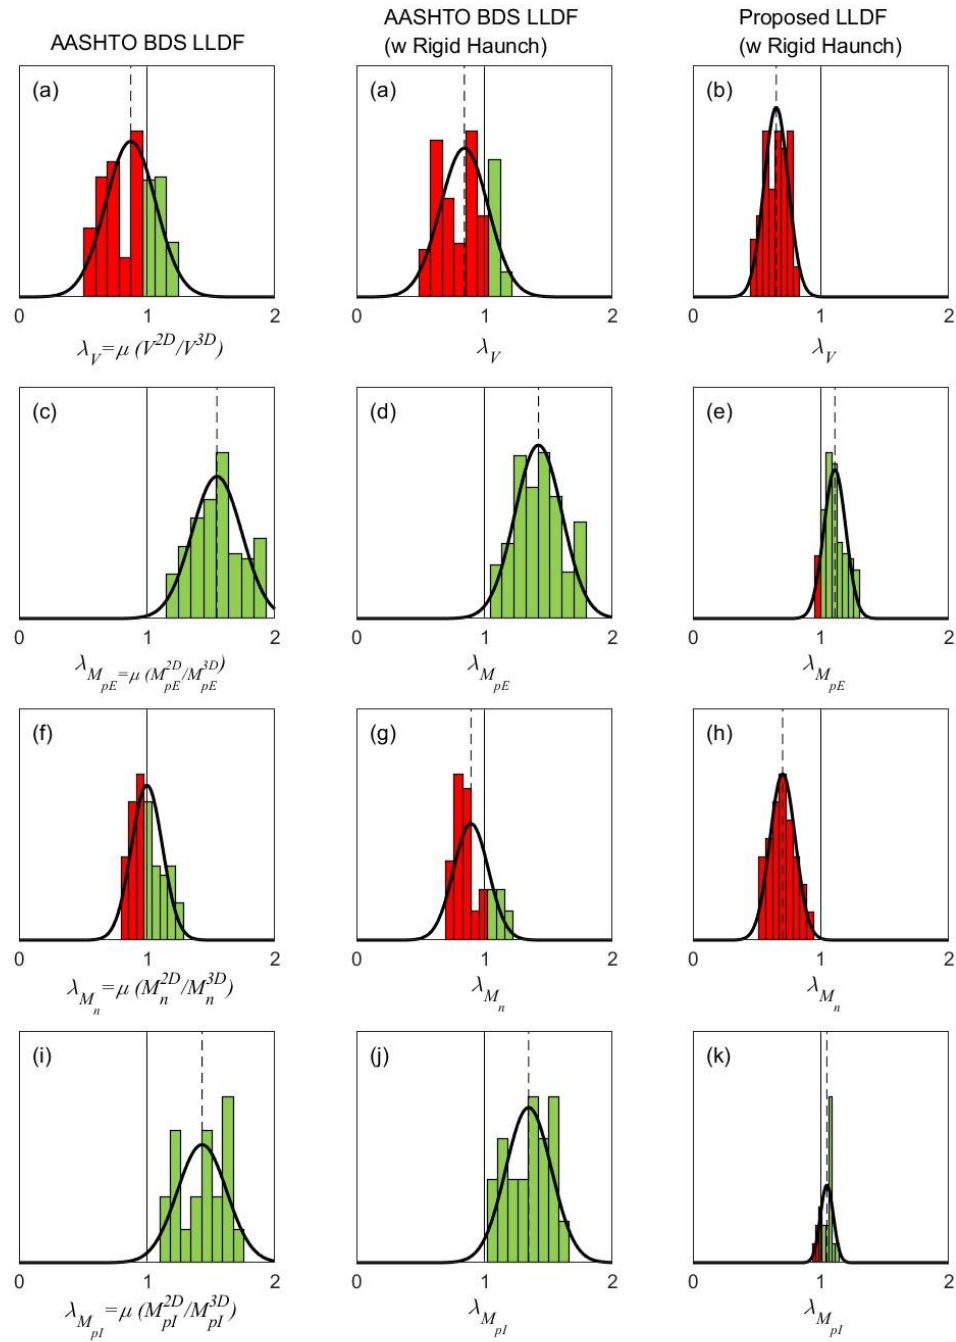

Figure 50. Trend of shear bias $\lambda_{V,avg}$ and COV for different LLDF formulas

Figure 51. Trend of exterior positive moment bias $\lambda_{M_{PE,avg}}$ and COV different LLDF formulas

Figure 52. Trend of negative moment bias $\lambda_{Mn,avg}$ and *COV* different LLDF formulas

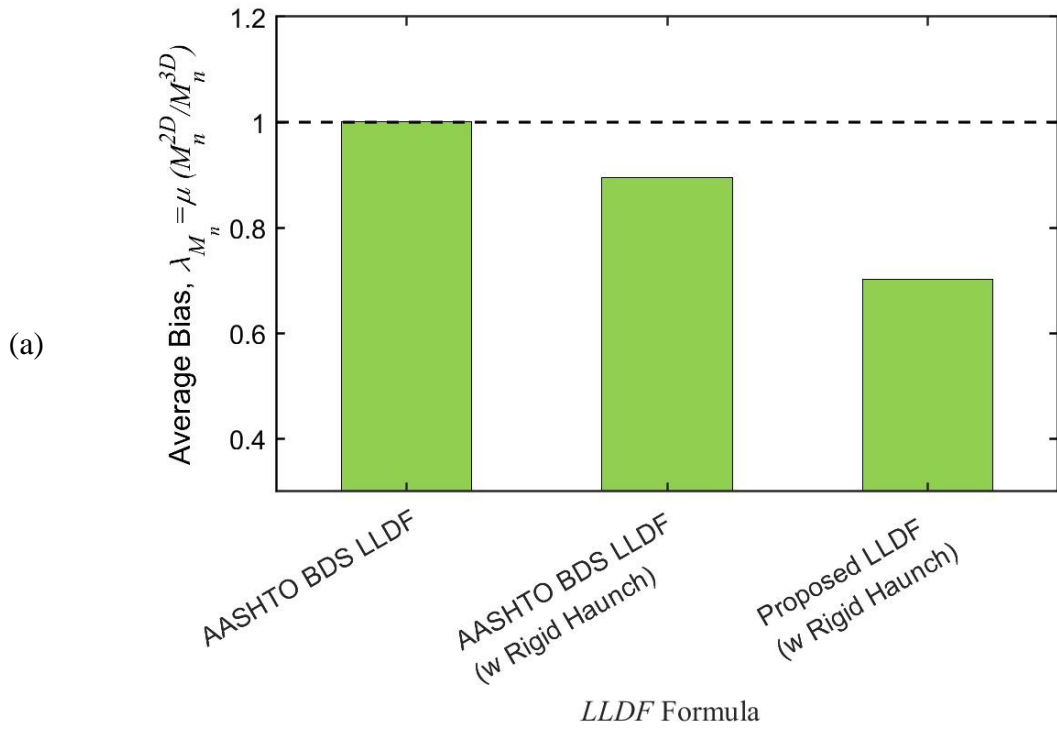

Figure 53. Trend of interior positive moment bias $\lambda_{M_{pl,avg}}$ different LLDF formulas

The previous figures are based on all results from the parametric study including 1-, 2-, and 3-barrels. To study the accuracy of the predictions for each group of cases, Figure 54, Figure 55, and Figure 56 are plotted for the 1-, 2-, and 3-barrel cases, respectively. It can be seen that the aforementioned observations hold true for all three groups. The proposed formula produces predictions with less scatter for all cases than AASHTO-LRFD BDS predictions. The average bias (λ) is clearly closer to 1.0 for positive moments (M_{pE} and M_{pI}) but not as close to 1.0 for the shear forces and negative moments (V and M_n).

Proposed Formula

Based on the above discussions, it is proposed that the following formula be used to distribute wheel loads in the direction perpendicular to traffic:

$$E = \xi_{SA}(92 + 1.15 H + 0.3 S) \quad [20]$$

Where, ξ_{SA} is a straining action coefficient equal to 1.0 for positive moment sections (M_{pE} and M_{pI}) and equal to 0.6 for shear and negative moment sections (V and M_n). This formula is evaluated in the next section using a structural reliability criterion to ensure that it conforms to AASHTO-LRFD BDS safety levels. It is also compared with AASHTO-LRFD BDS LLDF formula (Equation [17]).

For the sake of comparison between the proposed formula (Equation [20]) and AASHTO's LLDF formula (Equation [17]), a culvert with a span length equal to 10 ft. with fill depths equal to 0 ft., 1 ft., and 2 ft. are considered. Both methods use the same formula in the direction perpendicular to traffic (Equation [16]), and therefore are not evaluated. For the case of a fill depth equal to 0 ft., Equation [17] results in the following distribution width perpendicular to traffic:

$$\begin{aligned} E &= 96 + 1.44 S \\ &= 96(\text{in.}) + 1.44 \times 10(\text{ft}) = 110.4 \text{ in.} \end{aligned}$$

The proposed formula, on the other hand, produces the following distribution width for positive moments:

$$\begin{aligned} E &= \xi_{SA}(92 + 1.15 H + 0.3 S) \\ &= 1.0 \times [92(\text{in.}) + 1.15 \times 0(\text{in.}) + 0.3 \times 10(\text{ft}) \times 12(\text{in./ft.})] \\ &= 128 \text{ in.} \end{aligned}$$

and the following width for shear force and negative moments:

$$\begin{aligned} E &= 0.6 \times [92 + 1.15 \times 0(\text{in.}) + 0.3 \times 10(\text{ft}) \times 12(\text{in./ft.})] \\ &= 76.8 \text{ in.} \end{aligned}$$

The corresponding values for fill depths equal to 1 ft. and 2 ft. can be found in Table 6.

Table 6. Comparison of distribution width predictions

Fill Depth	AASHTO-LRFD BDS Equation [17] (in.)	Proposed Formula Equation [20] (in.)		Difference (%)
	M_{pE} , M_{pI} , V and M_n	M_{pE} and M_{pI}	V and M_n	
0	110.4	128.0	76.8	+15.9% and -30.4%
1	110.4	141.8	85.1	+28.4% and -22.9%
2	110.4	155.6	93.4	+40.9% and -15.4%

Reliability Assessment of Live Load Distribution Formulas

Reliability Evaluation

Reliability index (β) values were evaluated for all 273 culverts considered in this study. It was evaluated for both AASHTO-LRFD BDS LLDF formula (Equation [17]) and for the proposed LLDF formula (Equation [17]) from the current study. Figure 57 shows a plot of these results for AASHTO-LRFD BDS LLDF formula (Equation [17]). The four plots are for the following straining actions: shear force (V) positive moment in exterior span (M_{pE}) negative moment (M_n) and positive moment in interior span (M_{pI}) (refer to Figure 15 for the corresponding locations). It should be noted that for shear forces and negative moments, the minimum (i.e., critical) value of the two β -values to the left (V_{nl} or M_{nl}) and to the right (V_{nr} or M_{nr}) of the interior support was selected. Figure 58 shows the same plots for the cases evaluated using the proposed LLDF formula (Equation [20]).

It can be seen from the results in Figure 57 that AASHTO-LRFD BDS LLDF formula is both inconsistent and in some cases unconservative. Specifically, the AASHTO-LRFD BDS LLDF formula produces highly conservative β -values for positive moment sections (M_{pE} and M_{pI} , $\beta \gg 3.5$), whereas it produces β -values that are scattered around 3.5 for sections close to the support (V and M_n). This scatter includes many cases where $\beta \gg 3.5$ for V and M_n critical sections. In addition to not conforming to AASHTO-LRFD's target reliability index (β_{target}) it introduces an inconsistency in culverts designed or load rated using this LLDF formula.

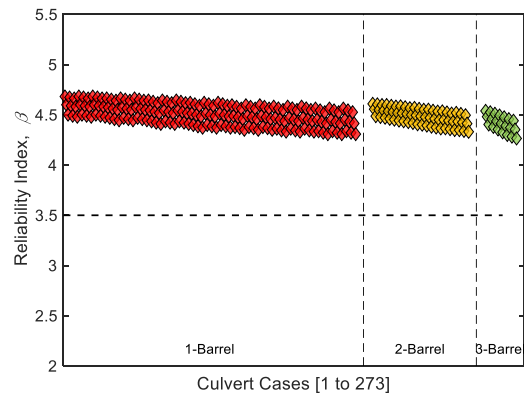

Conversely, Figure 58 shows a more consistent distribution of β -values for all straining actions considered in this study. For all positive and negative moments considered in this study (M_{pE} , M_n and M_{pI}), β -values are consistently at or slightly above AASHTO-LRFD's target reliability index (β_{target}) of 3.5. Furthermore, β -values for the shear force (V) were consistently above β_{target} . The higher scatter in β -values for shear forces is attributed to the inherently higher variability of our ability to predict shear resistance, as reflected by a COV of 10% compared to only 6% for flexure. Furthermore, shear forces occur due to either one axle or two axles, with one of them close to the supporting wall. Therefore, the secondary distribution offered by the top slab should reflect two distribution widths, one for each axle, which is not easily implemented in an empirical formulation. The other straining actions are typically controlled by one axle position (two for negative moment, with one on each span) that are farther away from the supporting wall. Therefore, the secondary distribution width is more consistent in these cases and contributes to the superior performance of the proposed LLDF formula.

In summary, using the proposed LLDF formula results in more consistent predictions of straining actions for design and load rating of culverts. The benefits of using the proposed formula include removing unnecessary conservatism for positive moment straining actions (M_{pE} and M_{pI}) while at the same time greatly reducing the inconsistency of results for negative moments (V and M_n) and reducing the inconsistency of results for shear forces albeit to a lesser extent. In all cases, the proposed LLDF formula conforms to AASHTO-LRFD's target reliability index (β_{target}) of 3.5.

Application of Proposed LLDF Formula on Sample Culverts

In this section, the proposed LLDF formula is used in the load rating of two culverts that were selected to represent a small span (6 ft.) culvert and a long span (10 ft.) culvert. For both cases, straining actions are obtained using 2-D models loaded with wheel load pressures obtained using the proposed LLDF formula.

Figure 59. FE meshes for selected culverts: (a) 3-barrel 10 ft. × 7 ft., (b) 2-barrel 6 ft. × 4 ft.

Culvert Case #1 ($S = 10$ ft.)

This 3-barrel culvert was selected to have non-square barrel openings to test the applicability of the proposed LLDF for configurations different than those used in its development. The rectangular barrel opening is 10 ft. × 7 ft., and the dimensions of the slabs (10 in.) and walls (8 in.) were selected from DOTD standards (CCSM10R90_1). It was analyzed for three fill heights (0 ft., 1 ft., and 2 ft.) using the 2D model described

twice in this report. The first set of results came from a model in which wheel load pressures were applied based on AASHTO LLDF, while the second set of results was for the 2D model with wheel load pressures based on the proposed LLDF. Table 7 lists the distribution widths used in the 2D model analysis, which are identical to the values demonstrated earlier (see Table 6) because both culverts had a barrel width equal to 10 ft. even though there is a difference in barrel height.

Table 7. Distribution widths for Culvert Case #1

Fill Depth	AASHTO-LRFD BDS Equation [17] (in.)	Proposed Formula Equation [20] (in.)	
	M_{pE} , M_{pI} , V and M_n	M_{pE} and M_{pI}	V and M_n
0	110.4	128.0	76.8
1		141.8	85.1
2		155.6	93.4

Table 8 lists the straining action predictions obtained using both 2D models, in addition to those obtained using the more accurate 3D model. The 3D model predictions were obtained to serve as a reference for comparing both 2D model results. Table 9 shows the differences between the 2D model and the 3D model predictions. It can be seen that AASHTO LLDF produces overly conservative positive moment predictions that reach 64% over those obtained using the 3D model. Furthermore, shear forces and negative moments are unconservative, consistently underpredicted by up to -40% for shear forces and -20% for negative moments. Conversely, the proposed LLDF produced conservative results consistently, with overpredictions equal to 13% on average, with a maximum conservative prediction of 30.7% and a maximum unconservative prediction of -14.6%.

Figure 60 illustrates the improvements that the proposed LLDF introduces to CIP-RC box culvert analysis using 2D models.

Conclusions

Current Practice

The design and load rating of cast-in-place (CIP) reinforced concrete (RC) box culverts is currently performed using an empirical live load distribution (LLDF) formula to distribute truck wheel loads through earth fill onto the top slab of the culvert, using American Association of State Highway and Transportation Officials (AASHTO) Bridge Design Specifications (BDS). Following this procedure has resulted in challenges to designers all over the country. In Louisiana, this is exacerbated by an old detail that was used for the construction of many culverts that are currently in service. The old detail does not call for top (negative) reinforcement in the outside corners, which releases negative moments in outside corners, and thus increases straining actions in other parts of the culverts. Field inspections have not revealed any distress as predicted by the AASHTO-LRFD BDS, and an earlier study (LTRC Project 16-3ST) on a limited number of culverts revealed that culverts perform well under service conditions despite AASHTO-LRFD BDS data to the contrary.

Project Findings

Based on an extensive parametric study considering 273 culvert configurations covering key parameters known to influence culvert behavior, the following conclusions can be drawn. By comparing results from refined analysis, this study confirms that AASHTO-LRFD BDS predictions using Equation [16] and [17] are inconsistent; they are highly conservative for positive moment starting actions and sometimes unconservative for shear forces and negative moments. Therefore, a new LLDF formula is proposed for predicting straining actions of CIP-RC culverts with Louisiana old details (i.e., those with no top (negative) reinforcement in the outside corners). The proposed formula (Equation [20]) for distributing the wheel load in the direction perpendicular to traffic, along with AASHTO-LRFD BDS Equation [16] for distributing the wheel load in the longitudinal direction, were also used to predict the straining actions. Based on these predictions, a reliability study was conducted to investigate the performance of both LLDF formulas, revealing the following:

- Using the proposed LLDF formula results in more consistent predictions of straining actions for design and load rating of culverts by removing unnecessary conservatism for positive moment straining actions (M_{pE} and M_{pI}) while at the

same time greatly reducing the inconsistency of results for negative moments (V and M_n) and reducing the inconsistency of results for shear forces, albeit to a lesser extent.

- Unlike AASHTO-LRFD BDS LLDF formula, which produces a wide range of reliability index (β) values, including some cases where β is less than β_{target} of 3.5, all predictions using the proposed LLDF formula meet or exceed this β_{target} , and thus conform to AASHTO-LRFD's target safety level.

Recommendations

Based on the findings of this project, the research team recommends the adoption of the proposed formula (Equation [20]) for distributing the wheel load in the direction perpendicular to traffic, along with AASHTO-LRFD BDS Equation [16] for distributing the wheel load in the longitudinal direction for the design and load rating or cast-in-place (CIP) reinforced concrete (RC) box culverts.

$$E = \xi_{SA}(92 + 1.15 H + 0.3 S) \quad [20]$$

Where, H is the fill height in inches, S is the barrel span length in inches, and ξ_{SA} is a straining action coefficient equal to 1.0 for positive moment sections (M_{pE} and M_{pI}) and equal to 0.6 for shear and negative moment sections (V and M_n). In the longitudinal direction, it is recommended that the AASHTO-LRFD DBS distribution formula (Equation [16]) be used.

$$E_{span} = L_T + LLDF(H) \quad [16]$$

If the load rating of any culverts does not produce acceptable results, and load posting would be necessary, it is recommended that refined analyses be used while taking advantage of the modeling recommendations from Project 16-3ST [1].

Acronyms, Abbreviations, and Symbols

Term	Description
DOTD	Louisiana Department of Transportation and Development
HWA	Federal Highway Administration
ft.	foot (feet)
in.	inch(es)
LTRC	Louisiana Transportation Research Center
lb.	pound(s)
$COV(X)$	Coefficient of variation of random variable X
E	Distribution width perpendicular to the span (in.)
E_{span}	Distribution width parallel to the span (in.)
H	Depth of fill from top of culvert to top of pavement (in.)
L_T	Length of tire contact area parallel to the span (in.)
$LLDF$	Factor for distribution of live load (1.15 for this study)
Q_{DC}	Random load demand due to component dead loads
Q_{DW}	Random load demand due to wearing surface dead loads
Q_{EF}	Random load demand due to weight of earth fill
Q_{LL+IM}	Random load demand due to live loads plus impact
R_R	Random cross-sectional resistance
S	Clear span (ft for Equation [17] and in. for Equation [20])
η	Parameter for calibration of clear span length term in proposed formula
ξ_{LLDF}	Random variable representing variability due to LLDF formulas
ξ_{SA}	Straining action coefficient
λ_X	Bias of random variable X

Appendices

Appendix A

First Order Reliability Method (FORM)

FORM is based on a first order Taylor Series expansion of the limit state function, which approximates the failure surface by a tangent plane at the point of interest. It is not always possible to find a closed form solution for a non-linear limit state function or a function including more than two random variables. Hence, to convert a non-linear limit state function into simple polynomials, Taylor series (Eq. A-1) is used. The expansion of a function, $f(X)$ at a certain point a is given by;

$$f(X) = f(a) + (X - a)f'(a) + \frac{(X-a)^2}{2}f''(a) + \dots + \frac{(X-a)^n}{n!}f^n(a) \quad (A-1)$$

FORM uses this expansion to simplify the limit state function $g(Z_1, Z_2, \dots, Z_n)$ by considering the expansion of the Taylor series after truncating terms higher than the first order. The expansion is done at the actual design point X^* . The design point is on the failure surface $g(Z_1, Z_2, \dots, Z_n)$ as shown in the Figure A62 for the case of two variables in a non-linear limit state function.

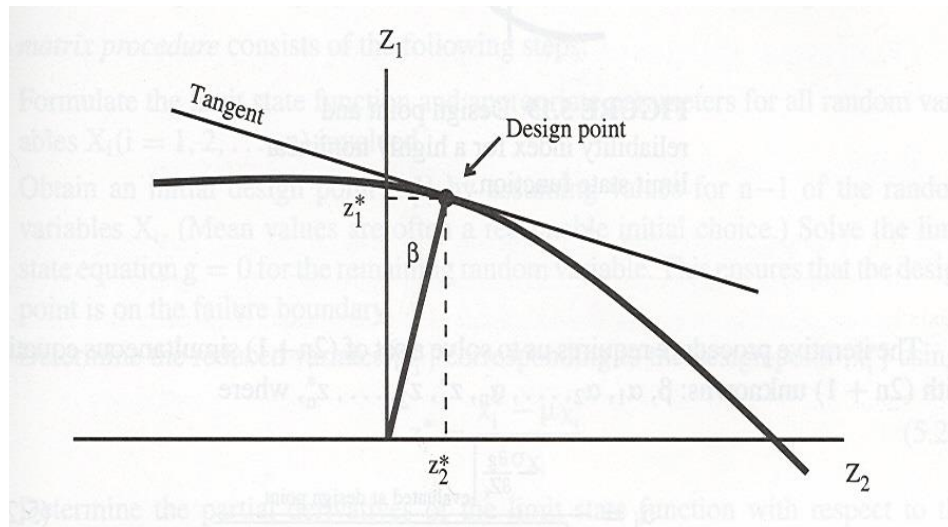

Figure A62. Reliability Index evaluated at design point [53]

To locate this point on the design space of $g(Z_1, Z_2, \dots, Z_n) = 0$, an iterative process is needed [53]. For the convergence of a design point through an iterative procedure, it requires solving a set of $(2n + 1)$ simultaneous equations with $(2n + 1)$ unknowns, $\beta, \alpha_1, \alpha_2, \dots, \alpha_n, Z_1^*, Z_2^*, \dots, Z_n^*$.

$$\alpha_i = \frac{-\frac{\partial g}{\partial Z_i} \Big|_{\text{evaluated @ design point}}}{\sqrt{\sum_{k=1}^n \left(\frac{\partial g}{\partial Z_k} \Big|_{\text{evaluated @ design point}} \right)^2}} \quad (\text{A-2})$$

$$\frac{\partial g}{\partial Z_i} = \frac{\partial g}{\partial X_i} \frac{\partial X_i}{\partial Z_i} = \frac{\partial g}{\partial X_i} \sigma_{X_i} \quad (\text{A-3})$$

$$\sum_{i=1}^n (\alpha_i)^2 = 1 \quad (\text{A-4})$$

$$Z_i^* = \beta \alpha_i \quad (\text{A-5})$$

$$g(Z_1^*, Z_2^*, \dots, Z_n^*) = 0 \quad (\text{A-6})$$

Where, α_i is a unit vector in the direction of a design point from the origin and Z_i^* is the design point in transformed space. Equation A-6 is a mathematical statement of the requirement that the design point must be on the failure boundary.

This procedure was derived with the assumption that the involved random variables are normally distributed. When the probability distributions for the variables involved in the limit state function are not normally distributed, it is required to calculate the equivalent normal values of the mean and standard deviation for each non-normal random variable. To obtain the equivalent normal mean (μ_X^e) and standard deviation (σ_X^e), the CDF and PDF of the actual function should be equal to normal CDF and normal PDF at the value of the variable X^* on the failure boundary described by $g = 0$. Mathematically, it can be expressed as:

$$F_X(X^*) = \Phi \left(\frac{X^* - \mu_X^e}{\sigma_X^e} \right) \quad (\text{A-7})$$

$$f_X(X^*) = \frac{1}{\sigma_X^e} \varphi \left(\frac{X^* - \mu_X^e}{\sigma_X^e} \right) \quad (\text{A-8})$$

Where, X is a random variable with mean μ_X and standard deviation σ_X and is described by a CDF $F_X(X)$ and a PDF $f_X(X)$, $\Phi(\cdot)$ is the CDF for the standard normal distribution, and $\varphi(\cdot)$ is the PDF for the standard normal distribution. Expressions for μ_X^e and σ_X^e can be obtained as follows:

$$\mu_X^e = X^* - \sigma_X^e [\Phi^{-1}(F_X(X^*))] \quad (\text{A-9})$$

$$\sigma_X^e = \frac{1}{f_X(X^*)} \varphi[\Phi^{-1}(F_X(X^*))] \quad (\text{A-10})$$

The basic steps in the iteration procedure [53] to obtain β are as follows:

1. Formulate the limit state function. Determine the probability distributions and appropriate parameters for all random variables $X_i (i = 1, 2, \dots, n)$ involved.
2. Obtain an initial design point $\{X_i^*\}$ by assuming values for n-1 of the random variables (mean values are a reasonable choice). Solve the limit state equation $g = 0$ for the remaining random variable, which ensures that the design point is on the failure boundary.
3. Equivalent normal mean (μ_X^e) and standard deviation (σ_X^e) are determined using

Equations A-9 and A-10 for design values corresponding to a non-normal distribution.

Determine the reduced variables $\{Z_i^*\}$ corresponding to the design point $\{X_i^*\}$ using:

$$Z_i^* = \frac{X_i^* - \mu_{X_i}^e}{\sigma_{X_i}^e} \quad (\text{A-11})$$

4. Determine the partial derivatives of the limit state function with respect to the reduced variables. $\{G\}$ is a column vector whose elements are the partial derivatives (Equation A-3) multiplied by -1.

$$\{G\} = \begin{Bmatrix} G_1 \\ G_2 \\ \vdots \\ G_n \end{Bmatrix} \quad \text{where, } G_i = -\left. \frac{\partial g}{\partial Z_i} \right|_{\text{evaluated at design point}} \quad (\text{A-12})$$

5. Estimate of β is then calculated using the following formula.

$$\beta = \frac{\{G\}^T \{Z^*\}}{\sqrt{\{G\}^T \{G\}}} \quad \text{where, } \{Z^*\} = \begin{Bmatrix} Z_1^* \\ Z_2^* \\ \vdots \\ Z_n^* \end{Bmatrix} \quad (\text{A-13})$$

6. The direction cosines for the design point to be used in the subsequent iteration are then calculated using:

$$\{\alpha\} = \frac{\{G\}}{\sqrt{\{G\}^T \{G\}}} \quad (\text{A-14})$$

7. Determine a new design point for $n-1$ of the variables using:

$$Z_i^* = \alpha_i \beta \quad (\text{A-15})$$

8. Determine the corresponding design point values in original coordinates for the $n-1$ values in Step 7 by:

$$X_i^* = \mu_{X_i}^e + Z_i^* \sigma_{X_i}^e \quad (\text{A-16})$$

9. Determine the value of the remaining random variable by solving the limit state function $g = 0$.

10. Repeat Steps 3 to 10 until β and $\{X_i^*\}$ converge.

Appendix B

Chi-Square Statistical Test: “Goodness-of-fit” Test

The Chi-Square test is often used to assess the “goodness-of-fit” between an obtained set of frequencies in a random sample and what is expected under a given statistical hypothesis. In order to decide which distribution is better for a particular random variable, the difference between actual observation values (observed frequencies) and theoretical distribution values (theoretical frequencies) is quantified. The steps required to determine the probability distribution of a random variable are given below.

1. Divide the observed data range into equal intervals.
2. Find the number of observations (Observed Frequency, n_i) within each interval that do not depend on the distribution type.
3. Assume different distribution types that will represent the random variable and find the theoretical distribution values (Theoretical Frequency, e_i) within each interval for the respective distributions. If a random variable, X , lies in an interval a to b such that $a < X \leq b$, then the Theoretical Frequency (e_i) for a certain distribution type is given by:

$$e_i = P(a < X \leq b) * N \quad (C-1)$$

4. where, N is the total number of observation (data points), and:

$$P(a < X \leq b) = P(X \leq b) - P(X < a) \quad (C-2)$$

5. The probability of X less than a or b , $P(X < a)$ and $P(X \leq b)$ is found using the CDF for the respective distribution. The CDF for different distribution types can be obtained from the literature.
6. For each interval, compute the difference between n_i and e_i (squared) as a ratio of e_i .
7. Compute the summation of differences (squared) as a ratio of e_i which is given as:

$$\sum_{i=1}^m \frac{(n_i - e_i)^2}{e_i} \quad (C-3)$$

where, m is the total number of intervals.

8. Calculate the degree of freedom (f) for Chi-Square test which is given by $f = m - 1 - k$, where k is the number of parameters required to describe a particular distribution. In this study, normal and lognormal distribution types are used and for these types $k = 2$.
9. The summation evaluated in Step 5 is compared to the Chi-Square distribution for

a certain significance level, α , which is always taken between 1% and 10 %.

10. If $\sum_{i=1}^m \frac{(n_i - e_i)^2}{e_i} < C_{\alpha, f}$, then the assumed distribution fits statistical data sufficiently.

11. $C_{\alpha, f}$ values are given in Table B1.

Table B1. CDF of the Chi-Square Distribution [50]

Table of the CDF of the Chi-Square Distribution with f Degrees of Freedom

Appendix C

Distribution Types Used in Current Study

Normal or Gaussian Distribution

If a variable is normally distributed, two quantities have to be specified: the mean (μ_X), which coincides with the peak of the PDF curve, and the standard distribution (σ_X), which indicates the spread of the bell curve. The PDF for a normal random variable X is given by Equation C-1.

$$f_X(X) = \frac{1}{\sigma_X\sqrt{2\pi}} \exp\left[-\frac{1}{2}\left(\frac{X-\mu_X}{\sigma_X}\right)^2\right] \quad (C-1)$$

There is no closed-form solution for the CDF of a normal random variable, but tables have been developed to provide values of the CDF for the special case in which $\mu_X = 0$ and $\sigma_X = 1$ [53]. These tables can be used to obtain values for any general normal distribution.

Figure C63 Graphical representation of Normal Distribution

Lognormal Distribution

The random variable X is a lognormal random variable (Figure C64) if $Y = \ln(X)$ is normally distributed, $F_X(x) = F_Y(y)$. The mean and standard deviation for Y are given by Equations C-2 and C-3.

$$\sigma_Y = \sigma_{\ln(X)} = \sqrt{\ln \left[\left(\frac{\sigma_X}{\mu_X} \right)^2 + 1 \right]} \quad (\text{C-2})$$

$$\mu_Y = \mu_{\ln(X)} = \ln(\mu_X) - \frac{1}{2} \sigma_{\ln X}^2 \quad (\text{C-3})$$

Figure C64 Graphical representation of Lognormal Distribution

Extreme Type I (Gumbel) Distribution

Extreme Type I is often used to describe maximum periodic event distributions. In this distribution type, the cumulative distribution function (CDF) is given by:

$$F_X(x) = e^{-e^{-\alpha(x-u)}} \quad (\text{C-4})$$

and the probability density function (PDF) is given by:

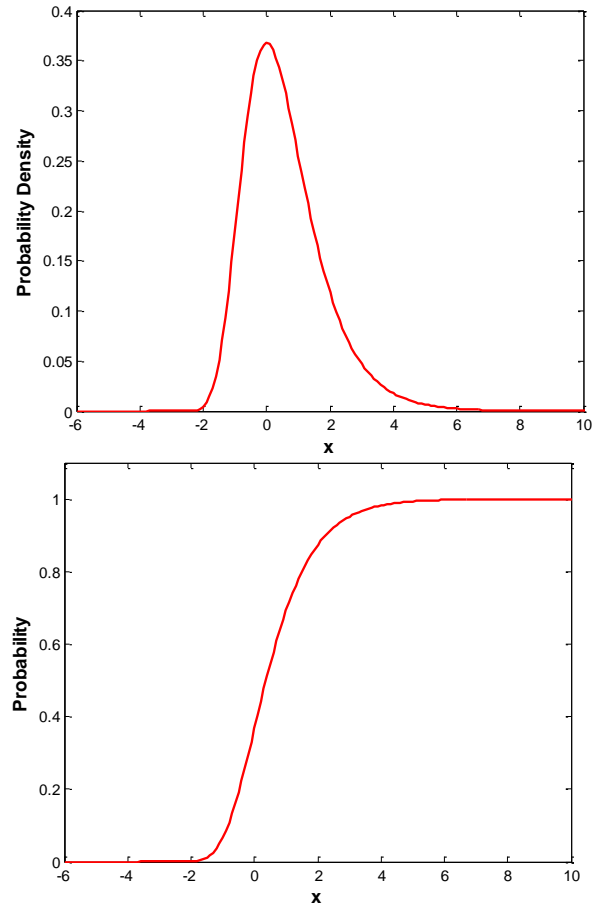

$$f_X(x) = \alpha e^{-e^{-\alpha(x-u)}} e^{-\alpha(x-u)} \quad (\text{C-5})$$

Approximate expressions that relate the mean and standard deviation to the scale and shape parameters of the distribution can be found in the literature (Benjamin and Cornell 1970).

$$\mu_X \approx u + \frac{0.577}{\alpha} \quad (\text{C-6})$$

$$\sigma_X \approx \frac{1.282}{\alpha} \quad (\text{C-7})$$

Figure C65 Graphical representation of Extreme Type I Distribution

Appendix E

Results from Parametric Study

This appendix provides the results from the parametric study of the 273 culverts considered in this study. The first set of results was obtained from the 3D shell element model.

Following this set, results from the 2D model using the AASHTO-LRFD BDS live load distribution formula are presented.

The reported results are:

$M_{pE}^{DC} =$	positive moment at 1 st exterior midspan due to component weight	$V_L^{DC} =$	shear force left of 1 st interior wall due to component weight
$M_{pE}^{EF} =$	positive moment at 1 st exterior midspan due to earth fill weight	$V_L^{EF} =$	shear force left of 1 st interior wall due to earth fill weight
$M_{pE}^{DW} =$	positive moment at 1 st exterior midspan due to wearing surface	$V_L^{DW} =$	shear force left of 1 st interior wall due to wearing surface load
$M_{pE}^{LL} =$	positive moment at 1 st exterior midspan due to live load	$V_L^{LL} =$	shear force left of 1 st interior wall due to live load
$M_{nL}^{DC} =$	negative moment at left of 1 st interior wall due to component weight	$V_R^{DC} =$	shear force right of 1 st interior wall due to component weight
$M_{nL}^{EF} =$	negative moment at left of 1 st interior wall due to earth fill weight	$V_R^{EF} =$	shear force right of 1 st interior wall due to earth fill weight
$M_{nL}^{DW} =$	negative moment left of 1 st interior wall due to wearing surface	$V_R^{DW} =$	shear force right of 1 st interior wall due to wearing surface
$M_{nL}^{LL} =$	negative moment left of 1 st interior wall due to live load	$V_R^{LL} =$	shear force right of 1 st interior wall due to live load
$M_{nR}^{DC} =$	negative moment at right of 1 st interior wall due to component weight	$M_{pI}^{DC} =$	positive moment at 1 st interior midspan due to component weight
$M_{nR}^{EF} =$	negative moment at right of 1 st interior wall due to earth fill weight	$M_{pI}^{EF} =$	positive moment at 1 st interior midspan due to earth fill weight
$M_{nR}^{DW} =$	negative moment right of 1 st interior wall due to wearing surface	$M_{pI}^{DW} =$	positive moment at 1 st interior midspan due to wearing surface
$M_{nR}^{LL} =$	negative moment right of 1 st interior wall due to live load	$M_{pI}^{LL} =$	positive moment at 1 st interior midspan due to live load

Units: lb.-in./in. for bending moment

Appendix F

Comparison of 2D and 3D Results

The following tables list the ratio of the extracted straining actions due to live loads from the 2D and 3D models for each case. The ratios listed in the following tables are for the following straining actions:

- 1-Barrel Cases
 - V_L = shear force left of 1st wall due to live load
 - M_{pE} = positive moment at 1st exterior midspan due to live load
- 2-Barrel Cases
 - V_L = shear force left of 1st wall due to live load
 - V_R = shear force right of 1st wall due to live load
 - M_{pE} = positive moment at 1st exterior midspan due to live load
 - M_{nL} = negative moment at left of 1st wall due to live load
 - M_{nR} = negative moment at right of 1st wall due to live load
- 3-Barrel Cases
 - V_L = shear force left of 1st wall due to live load
 - V_R = shear force right of 1st wall due to live load
 - M_{pE} = positive moment at 1st exterior midspan due to live load
 - M_{nL} = negative moment at left of 1st interior wall due to live load
 - M_{nR} = negative moment at right of 1st interior wall due to live load
 - M_{pI} = positive moment at 1st interior midspan due to live load

Note: each of the above listed variables is presented with superscripts indicating whether they results are from 2D- or 3D models. For example, M_{nL}^{2D} and M_{nL}^{3D} for the negative moment at left of 1st interior wall.
